## SUMMARY

## Summary

The cell cycle is a sequence of events enabling a cell to replicate and proliferate. Common landmark events in most eukaryotic cell cycles are duplication of the DNA, mitosis, and cell separation. The cell cycle lays the basis for development in multicellular organisms, and is of course important for cell or tissue renewal. Disregulation of the cell cycle can lead to uncontrolled growth and tumor formation.

Mitosis, or nuclear division, is tightly regulated to ensure proper segregation of nuclei to daughter cells. In budding yeast (*S. cerevisiae*), the timing of mitosis is coupled to cytokinesis by the action of the FEAR and MEN regulatory networks, which mediate exit from mitosis by activation of the phosphatase *ScCdc14*.

In this thesis, we investigate the function of homologs of these pathways in the filamentous fungus, *Ashbya gossypii*. This organism provides a unique cellular setting to study these matters, as it is a close relative of *S. cerevisiae* and shares most of the molecular machinery. However within its multinucleate hyphae, mitosis is uncoupled from cytokinesis, and cytokinesis is not followed by cell separation, thus leading to compartments containing 8-10 nuclei, separated by septa. We look into how exit from mitosis is affected in such a cellular environment where nuclei are free to divide without the spatial and temporal constraints as described in budding yeast, where each mitosis is followed by cytokinesis and cell separation.

In the first chapter, we study the core component of exit from mitosis signalling. We examine the

phosphatase *AgCdc14* and discover that its regulation is very similar to *S. cerevisiae*, with the phosphatase being sequestered within the nucleolus throughout interphase, and released during anaphase. Furthermore, we find it to be an essential component in nuclear cycle progression in *A. gossypii*, with nuclei in null mutants failing to undergo mitosis.

In the second chapter, we look at MEN homologs in *A. gossypii* and present evidence that the kinase cascade function of the pathway is likely conserved. We however show MEN homologs to be non-essential and play no role in *AgCdc14* regulation. On the other hand, we detect sporulation deficiencies in our mutants, which we could attribute to septation defects. More interestingly, we observe a partial mitotic arrest in MEN deficient cells. MEN homologs thus seem to have diverged from the primary role of their counter-parts in budding yeast.

The third chapter deals with homologs of the FEAR pathway. It had been previously suggested that, in primitive cells, the task of *Cdc14* phosphatase regulation may be solely bestowed upon this network of genes. We find this to hold true for *A. gossypii*, where we report severe mitotic defects upon deletion of FEAR homologs, and in particular, disruption of control over *AgCdc14* release.

We interpret the results as evidence for a simpler system regulating exit from mitosis in *A. gossypii* and lay out potential implications for the more complex system in *S. cerevisiae*.

## Remarks

- In this thesis, homologous genes bearing the same common name in different organisms are discussed. To avoid confusion, all instances of genes, ORFs or proteins are written with a prefix indicating the species or class in mind. For example, *AgCdc14* is the *Ashbya gossypii* ortholog of the *ScCdc14* protein in *Saccharomyces cerevisiae* and the mammalian isoforms *mCdc14A* and *mCdc14B* (or *Mus musculus MmCdc14A* and *MmCdc14B*).
- Due to an ancient genome duplication in the *S. cerevisiae* lineage, many genes in *A. gossypii* have two orthologs in *S. cerevisiae*. In these cases, the *A. gossypii* gene will be named after both homologs, starting with the one with the higher sequence similarity. For example, the lone ortholog of *ScDbf2* and *ScDbf20* in *A. gossypii* will appear in the text as *AgDbf2/Dbf20*. Genome duplication orthologs, correctly known as “ohnologs”, will sometimes be referred to as “twin” genes.
- When speaking of developing mycelia, the “age” of *A. gossypii* cells refers to the time elapsed after introducing spores to nutrients. The first hypha emerges from a germ bubble after 6-7 hours.
- A larger, general introduction serving as a basis for all three chapters is provided at the beginning of this thesis. The smaller introductions at the start of each chapter are thought to provide some further, more specific information, relevant for the understanding of the discussed experiments.
- A comprehensive abbreviation list merged with a glossary of selected terms and definitions can be found at the back of the manuscript.

## BACKGROUND

## Background

### Research on *Ashbya gossypii*: a short history

The filamentous ascomycete *Ashbya gossypii* was originally identified as a plant pathogen that caused fungal infections in a variety of tropical or subtropical plants, such as cotton of the *Gossypium* genus or citrus fruit (Ashby and Nowell, 1926). The mode of infection relies on the aid of insects (of the heteroptera sub-order), which have been found to carry spores or mycelium on their mouthparts and provide for the physical damage required for successful invasion (Frazer, 1944). Use of insecticide proved sufficient for eradicating widespread disease.

*A. gossypii* was later adopted by the food industry as a natural producer of vitamin B<sub>2</sub>, or riboflavin (Stahmann *et al.*, 2000). This vitamin has found its way into many fortified food products, and research on biotechnological aspects of production is still ongoing (Sugimoto *et al.*, 2010). Currently, the world's largest chemical company, BASF, manufactures more than 1000 tons of the vitamin annually using *A. gossypii* cultures (corporate website, April 2010).

In the early 1990s, first steps in genetic manipulation of *A. gossypii* were undertaken (Wright and Philippsen, 1991). The high efficiency of homologous recombination in this organism was soon recognized (Steiner *et al.*, 1995) and has since spawned the development of a wide range of molecular tools adapted from *Saccharomyces cerevisiae* protocols and based on the integration of PCR-generated DNA fragments (Wendland *et al.*, 2000; Dunkler and Wendland, 2007; Kaufmann 2009).

Intriguing similarities with *S. cerevisiae* on the nucleic acid sequence level were discovered early on (Altmann-Jöhl and Philippsen, 1996; Prillinger *et al.*, 1997) and ultimately led to the sequencing of the entire *A. gossypii* genome (Dietrich *et al.*, 2004). Comprehensive comparative analysis revealed insights into the evolutionary history of both organisms, including evidence of a whole genome duplication event in *S. cerevisiae*.

**Figure 1: Plant pathogen *Ashbya gossypii*.** (A) *A. gossypii* mycelium on AFM (*A. gossypii* full medium) plate after three days of growth at 30°C. Image to scale (scale bar depicts 1 cm). (B) Cotton boll of *Gossypium hirsutum*.

The availability of a fully annotated genome, combined with prior knowledge gained from decades of research on *S. cerevisiae*, paved the way for functional genomics in *A. gossypii*.

Special attention has been given to polar growth, cell septation and regulatory control as well as dynamics of nuclei, as these aspects of the life cycle show intriguing differences compared with *S. cerevisiae*. Lately, transcriptomics and proteomics approaches have been added to the growing repertoire of methods successfully applied in *A. gossypii* (manuscripts in preparation).

### The life cycle of *A. gossypii*

*A. gossypii* has a genome very similar to that of the budding yeast *S. cerevisiae*, however this highly conserved genetic make-up functions within a completely different setting. *A. gossypii* is haploid and propagates by strictly filamentous growth, producing asexual spores in the older regions of mycelia (when nutrients run low), thought to contain one nucleus each. In the natural environment these spores are spread with the aid of insects. Germination from the mid-region of these needle-like spores occurs after a few hours of contact with nutrients in an isotropic fashion, leading to a germ-bubble (figure 2, A). Up to 3 rounds of nuclear division can occur within such a germ-bubble before sufficient polarization factors can be recruited and the switch to polarized growth is made. Two hyphal tips, 4-5 mm in diameter,

**Figure 2: Life cycle of *A. gossypii*.** (A) Germ bubble stage. Age: approx. 4-6 hours. Green dots represent nuclei. (B) Bipolar germling. Age: approx. 9-12 hours. (C) Young mycelium with lateral branches. Age: approx. 14-18 hours. Cytoskeleton also depicted in blue (cMT network, nucleated at SPBs) and red (actin cables and patches, mainly at hyphal tips and septation sites). (D) Hyphae of mature, fast-growing mycelium. Tip-splitting from the age of approx. 24 hours on. (E) Early stage sporangia. Can be seen in older/inner regions of approx. 2-3 day old mycelia. (F) Mature sporangia. Occur in oldest regions of mycelium after 3-4 days of growth on full medium plate. Scale bar depicts 10  $\mu\text{m}$ .

emerge from opposite sides of the germ-bubble. Cells at this stage of development are known as bipolar germlings (figure 2, B). As the speed of the tip accelerates, new polarization sites are defined along the hyphae, leading to branches (figure 2, C). Septa are formed at these branching sites, but also along the hyphae, at an average distance of roughly 40  $\mu\text{m}$  (Wendland and Philippsen, 2000; Kaufmann and Philippsen, 2009). As the mycelium matures, growing tips eventually reach the maximum speed of 3.5  $\mu\text{m}/\text{min}$  after roughly 24 hours (Köhli *et al.*, 2008). Already from the speed of 1.5  $\mu\text{m}/\text{min}$  on, lateral distribution of growing tips is accomplished by tip-splitting (Knechtle *et al.*, 2003; Schmitz *et al.*, 2006; figure 2, D), rather than lateral branching. The average distance between septa is now approximately 70  $\mu\text{m}$ . Within 2-3 days (depending on nutrient content of medium), hyphal

compartments delimited by septa enter the next stage of the life cycle and start expanding to form sporangia (figure 2, E). It is within these bloated compartments that single nuclei are encompassed in rigid, needle-shaped, spores, measuring 25-35  $\mu\text{m}$  in length (figure 2, F). Upon rupturing of the plasma membrane and cell wall due to mechanical stress or osmotic pressure, the spores are released and the cycle begins anew.

### Nuclei and the nuclear division cycle in *A. gossypii*

One of the most striking differences between *A. gossypii* and *S. cerevisiae* concerns their growth morphology. *A. gossypii* has evolved extremely fast propagation on solid and in liquid nutrient sources. Maximum ratio of distance/surface is achieved by

tubular growth and septa are only laid down sparsely. This growth strategy, optimized for speed, provides a unique environment for the nuclei, which reside in a common cytoplasm. With basically the same set of genes as present in *S. cerevisiae* (Dietrich *et al.*, 2004), nuclei in *A. gossypii* have adapted with/to these circumstances, and display behaviour unique to this species.

Movement of nuclei in growing *A. gossypii* hyphae can be broken down into at least three individually contributing components (Alberti-Segui *et al.*, 2001; Lang *et al.*, 2010a): 1) Passive, cytoplasmic flow, caused by the constant forward-directed streaming of cytoplasm towards the expanding tip and balanced by fluid uptake in posterior parts of the hyphae. 2) Short range cMT-dependent oscillation, the precise advantage of which is still unknown. 3) Long range cMT-dependent nuclear migration, including by-passing of other nuclei and sometimes passing through developing septa. All cMTs in *A. gossypii* are nucleated at the spindle pole bodies (SPB), which are the only MTOCs present in this species (Lang *et al.*, 2010).

Mitosis in *A. gossypii* is not coupled to cytokinesis, which is why we speak of “nuclear division cycle”, or simply “nuclear cycle”, as opposed to “cell cycle”. Mitoses in growing hyphae are asynchronous, with neighbouring nuclei in different nuclear division cycle stages. Asynchrony is possibly actively promoted by the cell, as nuclei synchronized with MT-depolymerizing compounds return to asynchronous division within two hours (Gladfelter *et al.*, 2006).

Kinetics of mitosis seem to have adapted towards higher speed in *A. gossypii*. Anaphase in *A. gossypii* takes a maximum of 12 minutes and shows a constant spindle elongation speed throughout the entire duration (Alberti-Segui *et al.*, 2001) and thus seems to be much quicker than in *S. cerevisiae*, where anaphase has been shown to be anywhere between 16 and 35 minutes and with clearly bi-phasic kinetics (Yeh *et al.*, 1995; Straight *et al.*, 1997; Kahana *et al.*, 1995; Hoepfner D., referenced in Alberti-Segui *et al.*, 2001; Movshovich *et al.*, 2008; Zimniak *et al.*, 2009). The high speed of

mitosis in *A. gossypii* may serve to facilitate quicker adjustment of local nuclear density.

Spatial orientation of mitosis in *A. gossypii* is subject to less constraint than in *S. cerevisiae* (which has multiple mechanisms responsible for correct spindle positioning): Mitotic spindles can be established at virtually any angle relative to the growth axis (Alberti-Segui *et al.*, 2001; Lang *et al.*, 2010b). As anaphase progresses, the mitotic spindle straightens out along the hyphal growth axis.

Some important differences in the regulation of the nuclear division cycle have been discovered, compared to *S. cerevisiae*. Cyclins in combination with a persistent Cdk also appear to be a driving force in *A. gossypii*, however their mode of function is of different nature. Of the five cyclin homologs (3 of which are essential: *AgCln1/Cln2*, *AgClb1/Clb2* and *AgClb5/Clb6*), only *AgClb5/Clb6* displays D-Box dependent oscillations of protein levels throughout the nuclear division cycle (Gladfelter *et al.*, 2006b; Hungerbühler *et al.*, 2007). The others all remain in at constant levels within the nucleus throughout all nuclear cycle stages, with *AgCln1/Cln2* additionally localizing to the growing hyphal tip. It is proposed that alternating Cdk (*AgCdc28*) activity is primarily brought about by inhibitors, such as *AgSic1*, instead of recurring destruction and synthesis of cyclins. Nevertheless, the APC (of which all components are conserved) is needed for progression through the nuclear division cycle and is required for *AgPds1* degradation at the onset of anaphase (Gladfelter *et al.*, 2007). These findings likely reflect adaptations to the special requirements of individual nuclear regulation in a syncytium where exchange of factors between nuclei in different nuclear cycle stages is enabled. As a further illustration of adaptation to filamentous growth concerning mitotic regulation, there is also evidence of increased mitotic activity in proximity to septa (Helfer *et al.*, 2006). This would ensure that hyphae emanating from branches or forks (where septa are always observed) have sufficient nuclei to maintain growth.

## GENERAL INTRODUCTION

## General Introduction

### Exit from mitosis in *S. cerevisiae*

The following is an attempt to condensate the body of work discussed in recent reviews (Queralt and Uhlmann, 2008; Rock and Amon, 2009; De Wulf *et al.*, 2009). Statements, when not cited directly, will often stem from these reviews. The summarizing graph of the involved networks (figure 3) is a simplified representation based on various review figures (mainly Rock and Amon, 2009).

### ScCdc14 phosphatase, a key regulator

Exit from mitosis is a term coined to describe the cell cycle transition that controls inactivation or disassembly of the cellular machinery used during mitosis (such as the mitotic spindle), and the completion of cytokinesis and chromosome decondensation. In budding yeast, these events are characterized/enabled by a transition from high to low ScClb2-Cdk activity. This decrease is brought about in multiple steps. Cdk down-regulation is first initiated by APC<sup>ScCdc20</sup> (an E3 ubiquitin ligase with ScCdc20 as a targeting co-factor), which becomes active at the metaphase to anaphase transition and serves to mark various targets, such as the mitotic cyclins, for destruction by protease complex. However, because APC<sup>ScCdc20</sup> itself is dependent on ScClb2-Cdk activity, it cannot be sufficient to fully inactivate the Cdk (Geymonat *et al.*, 2002), as is required for successful mitotic exit.

Full reversal of Cdk activity is only achieved with the help of the phosphatase ScCdc14. Targets for dephosphorylation by ScCdc14 are ScCdh1 (a further APC co-factor involved in cyclin degradation), and ScSic1 (an inhibitor of Cdk). Dephosphorylated APC<sup>ScCdh1</sup> and Sic1 together eliminate all mitotic Cdk activity, ultimately leading to mitotic exit. Other aspects of mitosis influenced by ScCdc14 include rDNA condensation (Sullivan *et al.* 2004) and segregation (Granot and Snyder, 1991), likely via RNA polymerase I inhibition (Clemente-Balanco *et al.*, 2009), spindle stabilization and spindle midzone assembly (review: Rock and Amon, 2009). ScCdc14 is also involved in multiple

positive feedback loops (FEAR via securin: Holt *et al.*, 2008; MEN via ScCdc15: Jaspersen *et al.*, 2000), enhancing its own release kinetics and making the metaphase/anaphase transition more switch-like.

### A two clutch system leading to Cdc14 release

Regulation of ScCdc14 itself is well understood in budding yeast and appears to be largely based on localization control. During interphase, prophase and metaphase, ScCdc14 is sequestered in a substructure of the nucleus called the nucleolus (the site of rRNA synthesis), where it is retained by association with its inhibitor, ScNet1 (alternative name: ScCfi1; Visintin *et al.*, 1999), which is part of the RENT complex (Shou *et al.*, 1999). Release of ScCdc14 from this inhibition is mediated upon activation of separase (ScEsp1) and onset of sister chromatid separation. As a result, ScCdc14 spreads throughout the entire nucleus and also into the cytoplasm. This nuclear export is crucial for the completion of cytokinesis (Bembenek *et al.*, 2005). The association with ScNet1 appears to be largely controlled by phosphorylation status.

### The FEAR (ScCdc14 early anaphase release) network

The first, transient wave of ScCdc14 release is triggered by components of the so-called FEAR network (Stegmeier *et al.*, 2003). This loosely defined set of genes ultimately affects ScNet1 binding to ScCdc14 in a number of ways. The core signalling pathway is initially sparked via the activation of ScZds1 and ScZds2 by ScEsp1 at the very beginning of anaphase. ScZds1 and ScZds2 interact and downregulate the PP2A<sup>ScCdc55</sup> phosphatase. This may happen in a protein complex with ScEsp1, and likely via induction of conformational changes or post-translational modifications and not by direct inhibition, as protein abundance of ScZds1 and ScZds2 is quite low (Queralt and Uhlmann, 2008). ScSlk19 is also

**Figure 3: ScCdc14 regulation in *S. cerevisiae*.** Simplified schematic scheme showing important or established interactions. ScCdc14 release from the nucleolus during early anaphase is mediated by the FEAR network and leads to a surge in ScCdc14 activity that coordinates certain anaphase events. ScCdc14 release from the nucleolus in late anaphase is mediated by the MEN and results in sustained ScCdc14 activity and, ultimately, exit from mitosis. dSPB: daughter-bound SPB, mSPB: mother-bound SPB, P: phosphate group.

believed to contribute to this step, most likely in a complex with *ScEsp1* (Sullivan and Uhlmann, 2003). Interestingly, *ScSlk19* is a target substrate of *ScEsp1* (Sullivan *et al.*, 2001), however, proteolytic cleavage of *ScSlk19* by *ScEsp1* is not required for its role in the FEAR network (Stegmeier *et al.*, 2002, Sullivan and Uhlmann, 2003). PP2A<sup>*ScCdc55*</sup> is a type 2A phosphatase, consisting of *ScTpd3* as a scaffold, *ScPph21* or *ScPph22* as the catalytic subunit, and *ScCdc55* as the specificity providing regulatory subunit. In metaphase, PP2A<sup>*Cdc55*</sup> prevents premature *ScNet1* phosphorylation and subsequent *ScCdc14* activation. Its downregulation in anaphase leads to Cdk-dependent *ScNet1* phosphorylation and as such, *ScCdc14* release (Queralt *et al.*, 2006). As hinted, the major part of *ScNet1* phosphorylation is thought to be contributed by *ScClb2*-Cdk (Azzam *et al.*, 2004). Some evidence however has been collected that suggests a role within FEAR for the Polo kinase *ScCdc5* in *ScNet1* phosphorylation, placing it downstream of, or in parallel to *ScEsp1* (Stegmeier *et al.*, 2002; Visintin *et al.*, 2003 and 2008). Other evidence points to the possibility that *ScCdc5* acts via degradation of the Cdk inhibitor *ScSwe1* (Liang *et al.*, 2009). The precise role of *ScCdc5* in mitotic exit remains subject to debate, the resolution of which is hindered by objections concerning the tightness of conditional mutants and more importantly, by *ScCdc5*'s additional involvement in the MEN.

Two further members of the FEAR functional group are *ScSpo12* and *ScFob1*. *ScFob1* is not only involved in nucleolar silencing (Huang and Moazed, 2003), but is also an inhibitory element of the FEAR network and is proposed to stabilize the *ScCdc14*–*ScNet1* interaction during anaphase (Stegmeier *et al.*, 2004). This action is thought to be antagonized by *ScSpo12* (Stegmeier *et al.*, 2004). *ScSpo12* itself appears to be controlled by phosphorylation status: Phosphorylated *ScSpo12* likely helps dissociate *ScFob1* from the *ScCdc14*/*ScNet1* complex. The kinase thought to phosphorylate *ScSpo12* is the mitotic Cdk. The counter-acting phosphatase acting up until anaphase is believed to be *ScCdc14*, which is insofar interesting as that this would suggest phosphatase activity during sequestration in the nucleolus prior to anaphase (Tomson *et al.*, 2009). *ScCdc14* is only transiently released by FEAR and will return to the nucleolus in the absence of

MEN activity. Importantly, early anaphase release of *ScCdc14* is not essential for progression through the cell cycle in *S. cerevisiae*, but still crucial for certain aspects of chromosome separation such as spindle stabilization, as mentioned further up. In the absence of FEAR network function, cells undergoing anaphase show a loss of viability. These roles however probably require relatively little phosphatase activity (which may even be sufficiently provided by some ts-mutants at restrictive temperatures), and thus are less susceptible to deficiencies in *ScCdc14* release or phosphatase activity.

## The MEN (mitotic exit network)

Once *ScCdc14* has been transiently released by FEAR, the MEN has the role of maintaining this release, allowing successful exit from mitosis. The core components of MEN resemble a Ras-like GTPase signal transduction cascade, with the G-Protein *ScTem1* taking a central role. *ScTem1* localizes to the cytoplasmic side (Pereira *et al.*, 2000) of the daughter cell bound SPB during anaphase (Bardin *et al.*, 2000; summary provided in figure 4), together with its GTPase activating protein (GAP) complex *ScBub2*-*ScBfa1* (Pereira *et al.*, 2000). The GAP complex serves as an interface for the regulatory input of the Polo-like kinase *ScCdc5* on the MEN. *ScCdc5* has been shown to phosphorylate *ScBfa1*, inhibiting activity of *ScBub2*-*ScBfa1* and thus enhancing *ScTem1* signalling (Hu *et al.*, 2001). The importance of *ScCdc5* in mitotic exit is underlined by the resequestration of *ScCdc14* being heavily dependent on *ScCdc5* degradation by APC<sup>*ScCdh1*</sup> (Visintin *et al.*, 2008). *ScKin4*, a member of the proposed “spindle positioning checkpoint” (SPOC). Generally speaking, the wide-reaching branch of components upstream of *ScTem1* identified as playing a role in monitoring spindle position. Literature often includes the MEN within SPOC (Lew and Burke, 2003), and vice-versa (Amon and Bardin, 2001). The boundaries are not really clearly defined, as would be expected when trying to define sub-sets of complex networks for the sake of simplification or the joy of inventing acronyms), inhibits the MEN activation by *ScCdc5* (D'Aquino *et al.*, 2005; Pereira and Schiebel, 2005) by phosphorylating *ScBfa1* (Maekawa *et*

**Figure 4: Localization of core MEN components in *S. cerevisiae*.** Adapted from Bardin *et al.*, 2001. ScLte1 is present throughout the entire cell during G1, and localizes to the bud during S phase and mitosis. ScNud1 acts as an anchor for MEN components at the SPB. As the mitotic spindle forms, ScTem1 and ScBub2-ScBfa1 localize to the dSPB. During anaphase, ScCdc15 and ScDbf2-ScMob1 are recruited to both SPBs (various conflicting data exists). During late telophase, ScCdc15, ScDbf2 and ScMob1 also localize to the site of cytokinesis.

*al.*, 2007). This is one example of how the MEN integrates spatial monitoring of the dividing nucleus into the control of mitotic exit. A second example is the proposed function of ScLte1, a putative guanine nucleotide exchange factor (GEF) of ScTem1 (Shirayama *et al.*, 1994a; Shirayama *et al.*, 1994b). ScLte1, was long suggested to function as a sensory functional unit, due to its localization to the daughter bud cortex during anaphase (Bardin *et al.*, 2000), and was thought to activate ScTem1, moving into the daughter bud on the daughter bound SPB upon correct elongation of the mitotic spindle. This however was often disputed, due to the lack of contribution to mitotic exit of ScLte1's GEF domain, among other reasons (Geymonat *et al.*, 2002; Yoshida *et al.*, 2003). It is also argued that ScTem1 has such high intrinsic guanine nucleotide exchange activity that no GEF would be required (Geymonat *et al.*, 2002). Recently, additional evidence against the spatial switch model emerged showing that more likely, ScLte1 acts on mitotic exit by influencing the localization of ScBfa1 at the SPBs (Geymonat *et al.*, 2009). Exactly how this might work remains subject to speculation, and other investigations have uncovered even more complexity than previously expected, spanning different aspects of the developing bud. An example of how further factors are intertwined into the pathway is the polarity factor ScKel1 (and ScKel2), which is localized to the bud cortex (Philips and Herskowitz, 1998). It was shown to be a negative regulator of MEN and bind ScTem1 and ScLte1

independently (Höfken and Schiebel, 2002). ScLte1 affects ScKel1 localization (Geymonat *et al.*, 2009) and vice-versa (Seshan *et al.*, 2002).

To further propagate the MEN signal, active ScTem1 interacts with the kinase ScCdc15 (Asakawa *et al.*, 2001), which in turn activates the ScDbf2-ScMob1 kinase complex via phosphorylation of the kinase subunit ScDbf2 (Mah *et al.*, 2001). These components all appear to localize to both SPBs during anaphase and telophase (summarized in review by Bardin and Amon, 2001), but have also been shown to localize to the site of cytokinesis (Yoshida and Toh-e, 2001). It has also been shown that ScDbf2-ScMob1 enters the nucleus during telophase (Stoepel *et al.*, 2005). Tethering to the SPBs occurs on SPB component ScNud1 (Gruneberg *et al.*, 2000). MEN components residing on the daughter cell-bound SPB (dSPB) are proposed to be mainly controlled by dSPB-localized ScBfa1-ScBub2. MEN components on the mSPB are negatively regulated by Cdk (König *et al.*, 2010).

Although ScNet1 was identified in a screen for ScDbf2 substrates (Mah *et al.*, 2005), it is still unknown how the final kinase in the signalling cascade (ScDbf2) stimulates release of ScCdc14 from ScNet1. Recently it was discovered that one function of the ScDbf2-ScMob1 complex is to phosphorylate ScCdc14 at sites adjacent to its nuclear localization sequence, thereby retaining ScCdc14 in the cytoplasm (Mohl *et al.*, 2009). Return of ScCdc14 to the nucleolus after mitotic exit in *S. cerevisiae* is at least in part mediated by

*ScCdh1*-mediated degradation of *ScCdc5* (Visintin *et al.*, 2008). In contrast to the viability of FEAR mutants, cells without functioning MEN signalling fail to exit mitosis.

To summarize, exit from mitosis is very complex and full of functional redundancy, collateral action and feedback loops. This complexity is required for the described two-clutch release of *ScCdc14*. Why the cells have evolved such a two-clutch system could have two reasons (Bosl and Li, 2005):

First, these complex networks may serve to provide circuitry loops to remove distortion and noise from signalling, leading to a fluctuation-free gradual release of *ScCdc14*. Feedback loops have been proven to be effective in achieving stable signals in biological networks (Becskei and Serrano, 2000). Feedback is also of utmost importance in providing uni-directionality in the cell cycle. It has been shown that degradation of cyclins is in fact intrinsically reversible, and that only via feedback systems can such transitions be rendered irreversible (Lopez-Aviles *et al.*, 2009). This holds true for many instances of switch-like behaviour, however the abrupt events during mitosis rely particularly

heavily on such mechanisms (Holt *et al.*, 2008). Feedback loops may also generate oscillatory behaviour, providing a basis for cell-cycle dependent fluctuations of activity. Recently, an intrinsically oscillatory module controlling nucleolar release and resequestration of *ScCdc14* was discovered, of which *ScCdc15* (but not *ScSpo12*) was shown to be a component (Lu and Cross, 2010). Frequency of these autonomous oscillations is thought to be fine-tuned by Cdk to occur once per cell cycle.

Second, the two-clutch regulation of *ScCdc14* may have also developed to allow for MEN to play a role in spatial surveillance and monitoring of the position of the polarized mitotic spindle. As to how this additional level of control could have evolved, it has even been specifically suggested that “in a primitive cell, where the orientation of mitosis might be inconsequential, the FEAR network could represent the sole mechanism for *Cdc14* release, and the MEN emerged later coevolving with oriented cell division. [...] It is possible that the original FEAR control of mitotic exit became less effective during the evolution process to allow additional control by the MEN.” (Bosl and Li, 2005).

## AIM OF THESIS

## Aim of thesis

Understanding of the regulation of exit from mitosis in *S. cerevisiae* has progressed far, and many interactions and functions have been clarified to date. The overall impression is that multiple signals from various parts of the cell converge in these overlapping regulatory networks, and a wide array of outputs is produced, affecting different aspects of M to G1 transition. How this complex network consisting of so many components could have evolved has often been discussed (Bosl and Li, 2005; Lu and Cross, 2010). With this body of work, we address this question and attempt to gain insight into the functions of these networks in *A. gossypii*.

Specifically speaking, we investigate the roles of the *A. gossypii* homologs of the genes involved in exit from mitosis. We set out to answer whether or not the phosphatase *AgCdc14* plays a central role in this cell cycle stage transition, as it does in budding yeast. We also conduct experiments to determine the functions of the homologs of the upstream regulatory pathways, FEAR and MEN. Emphasis is placed on the requirement of these genes for successful mitosis and *AgCdc14* release. This is analyzed by in vivo microscopy on cells harbouring

a variety of fluorescent markers.

Generally speaking, we try to provide a snapshot of the evolution of this regulatory network within the *A. gossypii* lineage. The evolutionary distance between *A. gossypii* and *S. cerevisiae* is ideal for comparison: The species are close enough for entire functional groups of genes to be conserved, but distant enough to have developed fundamentally different survival strategies, using basically the same set of genes. We hope to find some answers to such questions as: Is *A. gossypii* a living example of an ancient, “primitive” cell? Why are the regulatory pathways in budding yeast so complex? Does the bulk of evolutionary pressure that formed this vast network stem from the need for spatial regulation and thus the integration of a wide range of inputs? Or does the complexity arise from the need for multiple feedback loops to dampen signal noise, create abruptness and irreversibility or to generate oscillatory behaviour? In the first case, one would expect the regulatory network to be less complex in a simpler setting without coordination between nuclear division cycles and cell separation, such as in *A. gossypii*.

## CHAPTER I

## CHAPTER I: AGCDC14 AND THE NUCLEUS

### Introduction

Due to our interest in the regulatory networks controlling exit from mitosis, a prior characterization of the central effector phosphatase *AgCdc14* was needed. To be able to study localization patterns of *AgCdc14*, precise knowledge of the spatial organisation of *A. gossypii* nuclei was needed, but not sufficiently provided by prior studies. To further refine our understanding of the structure of nuclei, we selected two genes for localization studies: 1) *AgNup49*, to visualize the nuclear membrane, and give us an idea of total nuclear volume, and 2) *AgNop1*, a prominent marker known to be localized in the nucleolus. Both genes had been extensively applied as subnuclear markers in *S. cerevisiae* studies, and proved to be of great use.

*ScNup49* is part of the so called *ScNsp1* complex (Grandi *et al.*, 1995), which is a component of

the core nuclear pore complex (NPC) machinery. The *ScNsp1* complex likely interacts directly with transport receptors (karyopherins) used to actively shuttle substrates larger than 40 kDa through the NPC. The complex may also help in adjusting the pore diameter (Melcak *et al.*, 2007).

*ScNop1* (known as fibrillarin in higher eukaryotes) is found in the nucleolus, as part of the small subunit processome complex, which is required for processing of pre-18S rRNA (Tollervey *et al.*, 1991). It is also shown to be a component of the so-called RENT (regulator of nucleolar silencing and telophase exit) complex (Shou *et al.*, 1999), together with other protein products such *ScNet1* or *ScSir2*. Like the acronym suggests, the RENT complex is important for *ScCdc14* sequestration (Visintin *et al.*, 1999), but also for other rDNA

**Figure 5: *ScCdc14* localization in *S. cerevisiae*.** (A) Release dynamics of *ScCdc14* during mitosis (adapted from Yoshida *et al.* 2002). (B) *ScCdc14* sequestered in nucleoli of interphase cells (adapted from Visintin *et al.* 1999). (C) *ScCdc14* localizes to SPBs (adapted from Yoshida *et al.* 2002). (D) *ScCdc14* localizes to bud neck (yellow arrowhead) (adapted from Bembenek *et al.* 2005).

related tasks, such as silencing (Straight *et al.*, 1999). *ScCdc14* activity is heavily dependent on its localization. Many known sites of action have been described in *S. cerevisiae* and we were interested in seeing whether localization patterns are conserved in *A. gossypii*. In budding yeast, *ScCdc14* nucleolar sequestering and release into the nucleoplasm during anaphase can be monitored in vivo, using *ScCdc14*-GFP fusions (Figure 5, A). Sequestration in the nucleolus can be readily shown by *ScNop1* co-localization (Figure 5, B). Using multiple fluorescent tags simultaneously, other, lesser pronounced localizations can be made out. For example, *ScCdc14* apparently finds its way to the SPBs (Figure 5, C), with SPB signal strength peaking during anaphase. Also, *ScCdc14* was shown to play a role at the bud neck in actomyosin ring contraction. The relocalization required for this task (Figure 5, D) is dependent on an NES motif. In *S. cerevisiae*, cells carrying a ts-allele of *ScCDC14* arrest in late anaphase with an elongated mitotic spindle when shifted to the restrictive temperature, (Pringle and Hartwell, 1981), due to failure in promoting exit from mitosis (Visintin *et al.*, 1998).

In this chapter, experiments addressing the conservation of the functional group surrounding *AgCdc14* in *A. gossypii* are discussed. This can be seen as a prerequisite for the investigation of the underlying regulatory pathways of this potentially pivotal phosphatase. Homologs of *ScCdc14* in other organisms have been reported, and functional analysis has resulted in varying findings. The mammalian ortholog, *mCdc14A*, is essential for cytokinesis (reviewed in Trautmann and McCollum, 2002), and the homolog in *S. pombe*, *SpClp1* is non-essential, but crucial for cell fission. We performed knock-out and localization experiments on *AgCdc14* to gain insight into its role within the unique environment of a cell that doesn't undergo cytokinesis. We hypothesized that the role of *AgCdc14* would likely somehow reflect that of *ScCdc14*, at least concerning its involvement in nuclear division, due to the high degree of conservation between the species. However, given the decoupling of cell division from the cell cycle and asynchronicity of the nuclear cycle in this organism, we wondered whether this gene was essential at all.

## Materials and Methods

### *Ashbya gossypii* media and growth conditions

*A. gossypii* media and culturing are described in Ayad-Durieux *et al.*, 2000, and Wendland *et al.*, 2000.

### *A. gossypii* transformation

*A. gossypii* transformation was performed as described in Wendland *et al.*, 2000.

### Strain and plasmid construction

All plasmids and strains used in this study are listed in supplemental tables 5 and 6. DNA manipulations were carried out according to *Molecular Cloning* protocols (Sambrook, 2001) with *E. coli* DH5 $\alpha$ F' as a host strain (Hanahan, 1983). PCR amplification was performed using standard methods and methods adapted from product descriptions with Taq DNA polymerase, using the Expand High Fidelity or the Expand Long Template PCR system (Roche Diagnostics). Oligonucleotides are listed in supplemental table 4 and were synthesized by Microsynth AG, CH-9436 Balgach. For recombination of plasmids and PCR products, both were co-transformed into the budding yeast host strain DY3 (*MAT $\alpha$  his3 $\Delta$ 200 trp1 $\Delta$ 63 leu2 $\Delta$ 1 ura3-52 $\Delta$ ) according to (Gietz *et al.*, 1995). Plasmids were isolated from yeast cells using the High Pure Plasmid Purification Kit (Roche Diagnostics) with a modified protocol as previously described (Schmitz *et al.*, 2006).*

To construct pMF8, the *AgNOP1* locus was amplified by high fidelity PCR from genomic DNA using the primers NOP1SpeIup and NOP1BamHI down. A BamHI/SpeI digest of the product was sticky-end ligated into a BamHI/SpeI digested pRS416 backbone, and verified first by enzyme digestion, then by sequencing of the cloned ORF.

pMF12 was constructed by homologous recombination in *S. cerevisiae* cells. pAGT211 was used as a template to generate an insertion cassette with homologous flanking regions using NOP1\_F5

and NOP1\_F2. The product was co-transformed into DY3 cells together with pMF8, and the resulting fusion plasmid was isolated and verified by enzyme digestion and sequencing of the mCherry moiety as well as the C-terminus of *AgNOP1*.

To generate the *AgNup49-GFP GFP-AgTub1* strain, the plasmid pNUP49-yEGFP (courtesy of Sandrine Grava) was transformed into a GFP-*AgTub1* strain (courtesy of Claudia Lang).

*AgNop1-Cherry AgCdc14-GFP* was generated by transformation and genomic integration of a fragment produced by digestion of pMF12 with EcoRI and SpeI (and additionally DraI and BspHI to disrupt ARS dependent replication of the plasmid). Homokaryons were not functional, so imaging was conducted in heterokaryotic mycelium.

To generate *AgNop1-Cherry AgH4-GFP AgTub4-YFP*, pMF12 was introduced into an *AgH4-GFP AgTub4-YFP* background and maintained by constant selection. Genomic integration was not attempted, due to the non-functionality observed in *AgNop1-Cherry AgCdc14-GFP* homokaryons.

Deletion cassettes for homologous recombination as used for all gene deletions in this thesis were generated by PCR using either pAGT100 (NAT1 marker), pAGT120 (LEU2 marker) or pAGT140 (GEN3 marker) as templates, and oligonucleotide primer pairs with 50 bp homologous flanking sequences for integration. Deletion cassettes were additionally purified prior to transformation, mostly by ethanol precipitation, or via PCR product purification columns (Roche Diagnostics).

Transformation of *A. gossypii* first leads to heterokaryotic cells, which contain both of transformed and wild-type nuclei. Homokaryotic mycelia are obtained by isolating single spores which normally carry a single nucleus. Verification of all deletion strains was carried out by analytical PCR, using primer pairs designed to amplify 5' and 3' integration boundaries, as well as wild-type (non-integrated) corresponding regions as controls. Gel scans of verification reactions are provided at the end of the thesis.

For verification of fluorescent protein fusion transformants generated with plasmid digests,

verification PCR primers were designed to amplify 1) the fusion boundary, 2) a non-integrated region of the plasmid (to be able to rule out a propagation of undigested plasmid leading to resistance toward selective compound), 3) the corresponding N- or C-terminus of the wt allele, and 4) (if feasible) a product demonstrating integration of the selection marker into the genome. Latter is not always possible if the distance from the marker to the edge of the cloned genomic sequence is too large for amplification via PCR, as is the case on the pNup49-yEGFP plasmid.

Selective conditions were maintained with 200 µg/ml Geneticin/G418 Disulphate (ForMedium Ltd. for GEN3 marker), 50 µg/ml clonNAT (Werner BioAgents, for NAT1 marker) or ASC-Leucine (Michael Köhli, doctoral thesis, for LEU2 marker).

## Fluorescence microscopy and image processing

For microscopy, an Axioplan2 microscope equipped with the objectives Plan-Apochromat 100x/1.40 NA Oil DIC and Plan-Apochromat 63x/1.40 NA Oil DIC (Carl Zeiss AG, Feldbach, Switzerland) and appropriate filters (Zeiss and Chroma Technology, Brattleboro, VT) was used. The light source for fluorescence microscopy was a Polychrome V monochromator (TILL Photonics GmbH, Gräfelfing, Germany). Images were acquired at room temperature using a cooled charge-coupled device camera CoolSNAP HQ (Photometrics, Tucson, AZ) with MetaMorph 6.2r5 software (Molecular Devices Corp., Downingtown, PA). For fluorescence images, multiple planes with a distance between 0.5 and 1 µm in the Z-axis were taken. Raw image processing was performed with MetaMorph6.2r5 software. Z-stacks were optionally deconvolved with the built-in nearest neighbor algorithm and compressed by maximum or average projection with Stack Arithmetic and saved as 8-bit grayscale or RGB TIFF files. Further processing for thesis figures and all measurements were carried out with ImageJ (Wayne Rasband, National Institute of Health), using the 4D hypervolume viewer plugin. Channel overlays and cropping were performed with Photoshop CS2 (Adobe Systems, Mountain View, CA). For in vivo image acquisition, glass

slides were prepared covered with 0.6 ml of ASC or ALF medium (ASC medium with low fluorescence YNB, Sunrise Scientific Products) supplemented with 1% agarose, upon which small pieces of mature mycelium from the border of *A. gossypii* colonies or young mycelia cultured in liquid medium were placed and left to recover for at least two hours. 30 µl of ASC or ALF was added to mycelium before cells were covered with a coverslip for image acquisition. Such slides are also referred to as time-lapse slides, or TL slides.

## Bioinformatic analysis

Protein alignments were performed with sequences retrieved from the Ashbya Genome Database (AGD, Gattiker *et al.*, 2007) and the *Saccharomyces* Genome Database (SGD, Nash *et al.*, 2007).

Cdk motifs were predicted using the Fuzzpro tool of the EMBOSS suite (Rice *et al.*, 2000) and the search patterns [ST]-P-x-[KR] and [KR]-[ST]-P. Automatization to scan the entire genome was implemented using a custom PERL script written with Crimson Editor 5.70 (Ingyu Kang), running natively on a UNIX server hosting EMBOSS.

Domain predictions were run individually using InterProScan (Hunter *et al.*, 2009) and combined with predictions delivered by SGD.

Orthologs of *S. cerevisiae* genes in other organisms than *A. gossypii* were determined using psiBLAST ([www.ebi.ac.uk/Tools](http://www.ebi.ac.uk/Tools), Altschul *et al.*, 1997).

Amino acid sequence identity calculations and graphical alignments were produced with the multiple sequence alignment tool of the Clone Manager 7 Suite (Scientific and Educational Software, Cary, NC), using progressive assembly with default parameters.

All oligonucleotide sequences were chosen with optimized annealing characteristics using the primer design tool of the Clone Manager 7 Suite (Scientific and Educational Software, Cary, NC).

## Results

### Compartments of the *A. gossypii* nucleus

In previous studies focussing on the *A. gossypii* nuclear cycle (Gladfelter *et al.*, 2006; Helfer and Gladfelter 2006; Hungerbuehler *et al.*, 2007; Gladfelter *et al.*, 2007) a variety of components involved with or localizing to nuclei have been investigated. Nevertheless, our knowledge on the structure of the nuclei has remained somewhat basic, and due to the sub-nuclear phenomena dealt with in this work a more detailed picture of the *A. gossypii* nucleus was required.

To gain a better understanding on the dimensions and shape of the entire nucleus, we decided to localize the putative nuclear pore complex component AgNup49. The *A. gossypii* ORF shares 54% overall amino acid sequence identity with its predicted syntenic *S. cerevisiae* ortholog, including a region of 75% identity composed of the last 200 C-terminal residues (of 383 total amino acids). A C-terminal fusion of yEGFP to AgNup49 was introduced into a strain already harbouring GFP-AgTub1 (courtesy of Claudia Lang). GFP-AgTub1 was known to have an easily distinguishable signal and was included in this experiment in order to help identify mitotic nuclei.

AgNup49-yEGFP was shown to be unevenly distributed around the nuclear membrane (figure 6). No characteristic pattern or axis of symmetry could be made out in nuclei undergoing mitosis (figure 6, arrowhead). Measurements showed the mean projected area of the nuclear membrane to be  $3.44 \pm 0.56 \mu\text{m}^2$  (1 SD, N = 24) (this corresponds to diameters between 1.91 and 2.26  $\mu\text{m}$ ).

**Figure 6: The nuclear envelope in *A. gossypii*.** Localization of AgNup49-yEGFP and GFP-AgTub1 in mature, growing wild-type reference strain. Arrowhead indicates anaphase spindle. Maximum intensity projection of 5 planes with 1  $\mu\text{m}$  Z-distance. Scale bar depicts 1  $\mu\text{m}$ .

The sub-nuclear compartment most important to our studies due to its role in exit from mitosis is the nucleolus. We visualized the RENT complex within this distinct region of the nucleus by constructing a C-terminal fusion of the putative RENT component AgNop1 (which is 93% identical with its *S. cerevisiae* ortholog) with mCherry. This construct was introduced into a AgH4-GFP AgTub4-YFP background in order to be able to determine the position of the nucleolus relative to the non-nucleolar DNA within the nucleus. Heterokaryotic mycelia still containing wt copies of AgNop1 were used for the experiments, as AgNop1-mCherry did not prove to be functional on its own.

Fluorescent imaging showed AgNop1-mCherry to occupy a distinct space within the nucleus, clearly distinguishable from that of AgH4-GFP (figure 7). Mean areas occupied by the projections of these two markers were calculated to be  $1.28 \pm 0.51 \mu\text{m}^2$  (1 SD, N = 50) for AgNop1-mCherry and  $2.04 \pm 0.60 \mu\text{m}^2$  (1 SD, N = 50) for AgH4-GFP. The size ratio is similar to that observed in *S. cerevisiae*. Also, the nucleolus trails behind the rest of the nucleus during anaphase and divides at a later stage than the nuclear DNA. This is also concurrent with what is known about *S. cerevisiae* nucleoli (Granot and Snyder, 1991).

The measurements done on AgH4-GFP, AgNup49-yEGFP and AgNop1-mCherry are summarized as a basic scheme of a typical interphase nucleus (figure 8) in which mean size ratios were maintained graphically. As AgTub4YFP was also co-localized together with AgNop1-mCherry and AgH4-GFP, its position in relation to the other components could also be included in the scheme. We observed that AgTub4-YFP was generally localized adjacent to AgH4-GFP, but not necessarily opposite AgNop1-mCherry. In retrospective, we found that this basic model is accurately reflected in published EM images depicting nuclei, where the nucleolus is likely observable as a large and well defined electron-dense area physically separated from the SPBs (Lang *et al.*, 2010a, supplemental figure 1).

ScCdc14 functional group conserved in *A. gossypii* ScCdc14 was found to be highly conserved in *A.*

**Figure 7: The nucleolus in *A. gossypii*.** Subnuclear localization of AgH4-GFP and AgNop1-mCherry throughout nuclear division in growing hyphae. Image cropped individually for each timepoint. Scale bar depicts 1  $\mu$ m.

*gossypii*, with an amino acid identity value of 77% predicted. All important components known to be interact with or be directly downstream of *ScCdc14* in *S. cerevisiae* were found to have orthologs in *A. gossypii*, with sequence identity on the amino acid level ranging from 19% to 77% (table 1). All genes were found in syntenic locations, providing compelling evidence that low homology ORFs such as *AgSIC1* are true orthologs. When checking for motifs identified in *S. cerevisiae* to be sites phosphorylated by the cyclin dependent kinase (Cdk), we found that these motifs are also common sequence features in *A. gossypii*. We interpret the presence of these motifs as a possible indication of cell cycle related function. Notable are the extra occurrences of such motifs in *AgNet1/Tof2* and *AgCdc14* (table 1). In a more detailed look at the amino acid sequences (figure 9) we identified regions of particularly strong homology and ran protein domain predictions on all genes. All predicted domains in *ScCdc14* and *ScCdh1* were also predicted for the *A. gossypii* orthologs. Both the NES motif and the C-terminal NLS motif identified in *ScCdc14* were discovered to be at the same location within *AgCdc14*.

**Figure 8: Nuclear compartments of *A. gossypii*.** Overview providing size comparison of nuclear subcompartments. Area measurements were done using Z projections of growing hyphae. Size ratios are maintained in illustration.

In the case of *Net1*, where overall identity is only 33%, one highly conserved (67% ID) stretch was confined to the N-terminus, which has been shown to be responsible for *ScCdc14* binding in *S. cerevisiae* (Traverso *et al.*, 2001).

## AgCdc14 sequestration and release

Due to the high degree of conservation observed on the amino acid sequence level, we were interested to see to which extent functionality was conserved in *A. gossypii*. In order to study the behaviour of *AgCdc14*, a C-terminal GFP fusion was constructed (Katrin Hungerbühler, unpublished). *AgNop1-mCherry* was then additionally introduced into this strain to co-visualize the nucleolus. Time-lapse imaging series revealed different phases of *AgCdc14*-GFP localization during the nuclear division cycle (figure 10): During interphase, *AgCdc14* is sequestered within the nucleolus. The *AgCdc14*-GFP signal was shown to be restricted to within the area of *Nop1-mCherry*, but also to have a granular localization pattern, seemingly composed of multiple foci (figure 10, 0' 00"). During mitosis, *AgCdc14* is then progressively released from this confined space, and spreads to a total area of roughly 3.8  $\mu\text{m}^2$  (figure 10, 2' 30") which indicates localization throughout the entire nucleoplasm, according to the size estimates in figure BA. Coinciding with this release, *AgCdc14* also localizes to two distinct foci (figure 10, 3' 00") which then migrate apart as mitosis progresses (figure 10, from 4' 15" on). After mitosis is complete, *AgCdc14*-GFP then relocates to the nucleoli (figure 10, 14' 30").

As *ScCdc14* was described to localize to SPBs during anaphase in *S. cerevisiae* (Yoshida *et al.*,

<i>A. gossypii</i> ortholog					<i>S. cerevisiae</i> 1st homolog					<i>S. cerevisiae</i> 2nd homolog

2002), we hypothesised that this was also the case in *A. gossypii*. On this account, an AgCdc14-mCherry fusion was constructed (Katrin Hungerbühler, unpublished) and co-localized with AgTub4-YFP, an established component of the *A. gossypii* SPB (Lang *et al.*, 2010a). Single plane imaging confirmed that AgCdc14-mCherry indeed localizes to SPBs in anaphase nuclei (figure 11).

Additionally, a weak AgCdc14 signal is visible between the diving sister nuclei (figure 10, 7' 45'' and figure 11). It is unclear whether this is unspecific nucleoplasmic localization reflecting the closed mitosis that *A. gossypii* undergoes (Lang *et al.*, 2010a), or protein enrichment at the elongating spindle mid-zone.

AgCdc14-GFP was also found to localize to developing septa. In time-lapse series, protein levels did not appear to vary during ongoing septum constriction (figure 12). This septal localization suggests a substantial pool of AgCdc14 present in the cytoplasm.

### AgCdc14 is essential for progress through nuclear division cycle

To assess the role of AgCdc14 in the nuclear division cycle, the entire ORF was disrupted in a GFP-

AgTub1 strain. *Agcdc14Δ* mutants were not viable and ceased growth approximately 12-20 hours after spore inoculation (figure 13, A). Typically, growth arrest occurred in the bipolar or monopolar germling stage.

Investigation of GFP-AgTub1 in these deletion mutants indicated a malfunction of nuclear division (figure 13, B, top panel). Cells were shown to harbour only 2-3 nuclei at 8 hours after inoculation, compared to 10 or more in wt cells of comparable size. No nuclear division was recorded at this age in deletion mutants, implying that all mitotic activity was restricted to the first few hours of germination. It is plausible that these early germlings still contained residual AgCdc14 from the heterokaryotic mycelium used to harvest the spores for this experiment, and that the observed mitoses were only possible due to this “maternal effect”.

Nuclei in terminal *Agcdc14Δ* GFP-AgTub1 mutants were exclusively found in interphase (figure 13, B, top panel, yellow arrowheads). This became apparent when comparing with GFP-AgTub1 cells, where metaphase (bottom panel, red arrowhead) and anaphase nuclei (blue arrowhead) were easily distinguishable.

**Figure 11: Colocalization of *AgCdc14* and the SPB during anaphase.** Still image from a time-lapse series tracking *AgTub4*-YFP and *AgCdc14*-yEGFP in a dividing nucleus. Only a single plane was captured in order to reduce the interval between channels to roughly 3 seconds. Scale bar depicts 1  $\mu$ m.

Blue arrow: Spindle of anaphase nucleus. Scale bar depicts 1  $\mu$ m.

## Discussion

Nuclear substructures were shown to be conserved in *A. gossypii* and *S. cerevisiae*. We observed similarities not only in size and shape of the nuclear envelope and the nucleolus, but also in their behaviour during mitosis. The trailing of the *AgNop1*-Cherry signal behind that of *AgH4*-GFP is in agreement with observations in budding yeast (Granot and Snyder, 1991), and reflects distinctions made within the nucleus between different regions of the genome. Overall morphology of the *A. gossypii* nucleus is very much reminiscent of the *S. cerevisiae* counterpart.

The resemblance of the nucleolus in *A. gossypii* to that of *S. cerevisiae* hints at the possibility of retained functions. This is also suggested by the conservation observed on the amino acid level: homologs of all known RENT complex genes are present in *A. gossypii*.

The nucleolus apparently functions as the site for *AgCdc14* regulation by sequestration. We were clearly able to observe *AgCdc14*-yEGFPco-localized with *AgNop1*-Cherry leave the nucleolus during anaphase and spread throughout the nucleoplasm and to the SPBs. Likely, *AgCdc14* also exists at substantial concentrations in the cytoplasm, as we were able to observe clear signals at constricting septa. There, signal strength seemed independent of how close passing nuclei were. Quite possibly a significant cytoplasmic pool of *AgCdc14* would be needed to sustain such a clear signal. This septal localization likely corresponds to the proposed role of *ScCdc14* in actomyosin ring constriction at the bud neck (Bembenek *et al.*, 2005), where it is thought to dephosphorylate some yet unknown substrate involved in bud neck constriction. In a preliminary follow-up experiment, we looked at septum constriction (by means of *AgHof1*-GFP localization) in *Agcdc14* $\Delta$  germlings (supplemental figure 4, courtesy of summer intern Anaïs Sengler). Dynamics of *AgHof1*-GFP were unaffected, but a “maternal effect” of the heterokaryotic sporangia could not be ruled out.

*AgCdc14* was shown to play an essential role in nuclear division cycle progression in *A. gossypii*. Deletion mutants could undergo mitosis during a very narrow time-frame at the beginning of

germination (likely thanks to “maternal effect”), then all mitotic activity ground to a halt. Surprisingly, the observed nuclei all had single (or duplicated, but not separated) SPBs. This was unexpected, given that *ScCdc14* ts-mutants in budding yeast arrest in telophase with elongated mitotic spindles. In *A. gossypii*, *AgCdc14* may be needed in other parts of the cell cycle, such as prophase to metaphase transition or passage through S phase. This appears strange, considering that *AgCdc14* is clearly released (and thus activated) during anaphase. Perhaps some visible aspects of M to G1 transition such as spindle breakdown are possible with no (or little maternal) *AgCdc14*, however proper priming of the nucleus for the next cycle cannot take place. A look at homologs in other eukaryotes may give additional clues for interpreting this outcome.

In *S. pombe*, *SpClp1* (the *ScCdc14* homolog) plays an important part in G2 to M transition. The mode of action is however inhibitory on mitotic entry, and deletion mutants (which are viable) display premature entry into mitosis at shorter cell lengths than in wt (Trautmann *et al.*, 2001). *SpClp1* is already released from the nucleolus upon entry into mitosis and is also believed to inhibit Cdk activity. Upon release, *SpClp1* localizes to SPBs, the mitotic spindle, the actomyosin ring and can also be detected in the cytoplasm.

In mammalian cells, details on the system are still scarce. Mammals have two *ScCdc14* homolog isoforms, termed *mCdc14A* and *mCdc14B*. They localize to the centrosome and nucleolus respectively in interphase, but are then dispersed at onset of mitosis. *mCdc14A* appears to play a role in the regulation of the centrosome cycle, mitosis, and cytokinesis (Kaiser *et al.*, 2002), as well as meiosis I to meiosis II transition (Schindler and Schultz, 2009). *mCdc14B* does not impede anaphase onset, mitotic exit, or cytokinesis. Also, segregation of rDNA repeats remained intact in *mCdc14B* null mutants (Berdougo *et al.*, 2008). In conclusion, it seems that despite *ScCdc14*-related phosphatases being conserved, they are not individually needed in mammalian cells to segregate sister genomes or complete cell division.

As for other filamentous fungi, it has been shown

that *AnCdc14* is not essential in *Aspergillus nidulans*, which can grow and develop normally without this phosphatase (Son and Osmani, 2009). Orthologs of *ScCdc14* were found across virtually all eukaryotic species, indicating a central role of this phosphatase since ancient times. Homologs have been found not be essential components of mitotic regulation in all organisms, however, like in *S. cerevisiae*, this is the case in *A. gossypii*. *S. cerevisiae* is the closest relative of *A. gossypii* on the phylogenetic tree (James *et al.*, 2006) for which

published experimental data on this phosphatase is available. This close phylogenetic relationship is also reflected in the alignment of *AgCdc14* with homologs in selected species (figure 14). The terminal phenotypes of the null mutants are different in the *A. gossypii* and *S. cerevisiae*, for reasons not quite understood, however the timing of sequestration and release of the phosphatase from the nucleolus are the same, as are other localization characteristics. It will be interesting to investigate the regulatory basis of these events.

**Figure 14: Multiple sequence alignment of homologs of *AgCdc14* in selected species.** Identified by PsiBLAST. Blue regions in alignment indicate areas of significant similarity (window of 10 aas). Black lines are unique sequences.

## CHAPTER II

## CHAPTER II: MEN HOMOLOGS IN *ASHBYA GOSSYPII*

### Introduction

The fundamental question addressed in this chapter can be posed as such: Is there a functional MEN in *A. gossypii*? By strict definition the answer to this question would have to be “no”. By most circulating definitions, “mitotic exit” also includes successful cytokinesis, which automatically implies a direct coupling of cell division to the nuclear division cycle. This, as has been described before, is clearly not the case in *A. gossypii*. We therefore rather asked: Are the genes there and if so, what do they do?

It is difficult to imagine a conserved MEN exercising the same function in a syncytium as in the unicellular setting of budding yeast, for reasons laid out in the general introduction, the function in mind being the conditional facilitation of M-phase to G1 transition. We therefore decided to focus predominantly on finding out whether disruption of the system would lead to any detectable perturbations in the nuclear division cycle of *A. gossypii*. The experiments

described below were designed to gain as much information as possible on progression of nuclei through the division cycle, without ruling out any effect in unexpected cycle stages.

The most obvious readout of the MEN signalling pathway in budding yeast however is *ScCdc14* release. Disrupting core components of the MEN in *S. cerevisiae*, such as *ScTem1*, leads to an arrest of the cell cycle at the M/G1 transition, with elongated mitotic spindles, and *ScCdc14* still visibly retained within the nucleoli (figure 15, Shou *et al.*, 1999).

*AgCdc14* was shown to be crucial for progression through the nuclear division cycle, and the observed release patterns suggest that the mode of regulation described in *S. cerevisiae* may be conserved in *A. gossypii*. Here we present results of investigations into the effect of disrupting the putative MEN homologs on *AgCdc14* release and the effect on nuclear division stages in *A. gossypii*.

**Figure 15: *ScTem1Δ* terminal phenotype.** *ScCDC14-HA3 ScTem1Δ::GAL1-ScTEM1* cells switched to glucose medium (*ScTEM1* off) after  $\alpha$ -factor release (adapted from Shou *et al.*, 1999).

## Materials and Methods

### General

*A. gossypii* media, growth conditions, transformation, bioinformatic analysis, microscopy and strain verifications are as described in chapter I. Chitin staining (using Calcofluor White) was performed as described in Ayad-Durieux *et al.*, 2000.

### Strain and plasmid construction

All plasmids and strains used in this study are listed in supplemental tables 5 and 6. All methods are as described in chapter I.

Construction of the plasmid pMF1 was analog to that of pMF8, described previously, using the primers AgTEM1\_CL\_Up and AgTEM1\_CL\_Down. A HindIII/SpeI digest of the product was sticky-end ligated into a pRS416 backbone, and verified by enzyme digestion and sequencing. pMF2 was then constructed using pMF1 as a backbone, analogous to pMF12 construction outlined in chapter I, using AgTEM1\_F5 and AgTEM1\_F2 and the template pAGT241. The resulting fusion plasmid was isolated from the co-transformed yeast cells and verified by enzyme digestion and sequencing of the yEGFP moiety as well as the C-terminus of AgTEM1.

pMF3 was constructed in an analogous manner to pMF2, using the pre-existing plasmid clone (originally used for genome sequencing by Christine Mohr, documented in doctoral thesis) of the C-terminus of AgLTE1, pAG7638, as a backbone and the oligonucleotide primers AgLTE1\_F5 and AgLTE1\_F2 for fusion cassette amplification. Verification was via digestion and sequencing.

pMF10 was constructed in an analogous manner, using the AgPDS1 clone pAG11556 as a backbone, and pAGT211, combined with the primers PDS\_F5 and PDS1\_F2, to amplify the mCherry fusion cassette.

*A. gossypii* strains AgTem1-GFP and AgLte1-GFP were generated by transformation and genomic integration of fragments produced by digestion of pMF2 (with BssSI/BclI) and pMF3 (with BlnI) respectively. The AgPds1-Cherry AgCdc14-GFP

strain was obtained by transforming fragments produced by digesting pMF10 with ClaI and SpeI (as well as XmnI for ARS disruption). AgTem1-yEGFP, AgLte1-yEGFP and AgPds1-mCherry were all functional.

All deletion mutants were generated as described in chapter I.

### Anaphase measurements

The measurements of dividing nuclei as presented in figure 25 were performed by picking mycelium onto TL-slides, letting the cells recover for 2 hours, then imaging at 30 s intervals with 5 planes spaced 1  $\mu$ m apart. Only tip-splitting hyphae were taken into consideration as this reflects healthy cells growing at accelerated speeds. Nuclei undergoing mitosis were determined and were measured for maximal AgH4-GFP signal diameter at all time points. Nuclear cycle stages corresponding to the different diameters are illustrated in figure 16. Successful nuclear segregation is characterized by a fluctuating diameter, indicating independent movement of the sister nuclei.

**Figure 16: Anaphase measurements.** Depiction of how measured length corresponds to nuclear division cycle stages. From left to right: pre-anaphase (G2/prophase/metaphase), anaphase, post-anaphase, G1.

### Quantification of fractions of nuclei in different nuclear division cycle stages

Experiments presented in figure 27 were performed as follows: Tip-splitting hyphae were identified on TL-slides, indicating healthy growth, and short (8 minute) time-lapse movies were acquired, capturing

5 planes (1  $\mu\text{m}$  apart) for the *AgH4*-GFP signal, and 13 planes (0.5  $\mu\text{m}$  apart) for the *AgTUB4*-YFP signal at each time point (1 min time interval). The entire length of the movie was used to determine the category of nuclei in the third time frame, judging by the combined signals from the two channels acquired. Examples of nuclei assigned to different the categories are shown in figure 17.

**Figure 17: Nuclear division stage counts.** Example of time-lapse series used for classification of nuclei. Maximal projection and overlay of *AgH4*-GFP (green) and *AgTub4*-YFP (red) stacks. White border indicates time-frame used for count. Nuclei determined to be interphase (blue arrowhead), metaphase (yellow arrowheads, 2 SPBs paired on one nucleus, constant distance of  $1 \pm 0.2 \mu\text{m}$ ), and anaphase (violet arrowhead, linearly segregating SPBs). Scale bar depicts 10  $\mu\text{m}$ .

## *AgCdc14*-yEGFP vs. *AgPds1*-mCherry dynamics

To generate the data presented in figure 30, cells harbouring *AgPds1*-mCherry and *AgCdc14*-yEGFP were imaged over 20-30 minutes on low fluorescent (ALF) TL-slides (due to weak *AgPds1*-mCherry signal), allowing for rare instances where mitotic events could be entirely followed through. For *AgCdc14*-yEGFP measurements, a minimal polygon shape was determined (example in figure 29, left panel) which would capture the entire area of the yEGFP signal without being altered in size during the course of the series (to be able to compare the different time points). The intensity of all pixels within this area was measured and the individual values sorted to form a histogram of the data (figure 18). Going back to the raw images, intensity means were then calculated for sample areas within nucleolar foci (for core intensity of sequestered *AgCdc14*-yEGFP), within the nucleoplasm of anaphase nuclei (for intensity of released *AgCdc14*-yEGFP), and within the hyphae (for brightness of background fluorescence). In the example shown in figure 18, these values are 144, 128 and 104, respectively (blue dotted lines), and are used for the other timepoints later on. Based on these mean values, borders delimiting these categories were defined. For example, all pixels with intensities over 138, were deemed to represent sequestered *AgCdc14* (green markings), and could as such be counted. In this manner, numbers of pixels belonging to each category were determined for each time point, for each individual nucleus, and plotted against time. These resulting graphs could

**Figure 18: *AgCdc14* vs *AgPds1* measurements.** Pixel intensity histogram for one time point of one nucleus

then be combined on a common time axis and were scaled to correct for artefactual differences in signal intensities and boundary polygon shapes between experiments, leading to figure 30, “sequestered *AgCdc14*”. *AgPds1-mCherry* was treated in a analogous manner, but starting with a predefined 80 pixel large pseudo-circular area placed within the brightest part of the image, and without any classifications.

## Results

The entire set of *S. cerevisiae* genes involved in MEN is conserved in *A. gossypii*

Orthologs for all genes proposed to be involved in MEN signalling in *S. cerevisiae* were found to be annotated in the *A. gossypii* genome (Dietrich *et al.*, 2004). All orthologs are syntenic and computed amino acid identity values range between 19% for the SPB anchor (Lang *et al.*, 2010b) *AgNud1* and 79% for *AgCdc5* and *AgDbf2/Dbf20* (table 2). Generally (and cautiously) speaking, many orthologs of core components of the MEN such as *AgBub2*, *AgTem1*, *AgDbf2/Dbf20* or *AgMob1* exhibited high identity scores of over 70%, whereas orthologs of peripheral network components such as *AgKel1/Kel2*, *AgKin4/Frk1* had low identity values around 40%. Concerning notable differences in predicted Cdk phosphorylation motifs (which suggest a nuclear division cycle dependent role downstream of Cdk), *AgCdc15* was shown to have 5 motifs less than *ScCdc15*, whereas *AgDbf2/Dbf20*, *AgKel1/Kel2* and *AgKin4/Frk1* all had significantly higher numbers of predicted Cdk consensus sequences than their *S. cerevisiae* orthologs.

All domains predicted for MEN component in *S. cerevisiae* were also predicted for the *A. gossypii* orthologs (figure 19), suggesting that principle molecular functions are conserved for these genes. Notably, no regions of particular high homology

were calculated that do not overlap with domains of known function.

### Localization patterns of MEN orthologs are analogous to *S. cerevisiae*

Given the sequence level conservation of the *S. cerevisiae* MEN pathway in *A. gossypii*, we were interested to see if functionality was also conserved. To study the aspect of localization, we constructed C-terminal yEGFP fusions for the putative GEF *AgLte1* and GTPase *AgTem1*.

*AgTem1*-yEGFP was shown to localize to distinct foci reminiscent of *AgTub4*-YFP (figure 20), which is in agreement with the localization of *ScTem1* to SPBs in *S. cerevisiae*. In time-lapse recordings of growing hyphae, by studying their movement for up to half an hour, we were able to identify *AgTem1*-yEGFP foci of dividing nuclei (yellow arrowhead) and follow them through the course of mitosis. We were interested to see if asymmetric, polar localization of *AgTem1*-yEGFP occurred at any stage of the nuclear division cycle, as is the case in *S. cerevisiae*. This was shown not to be the case (figure 20, B). *AgTem1*-yEGFP was distributed to both foci evenly, with no loss or gain of signal over time.

*AgLte1*-yEGFP also exhibited a localization pattern analogous to that of its *S. cerevisiae* ortholog. Observing young mycelia up to 20 h in age, we

could see a strong localization of *AgLte1*-yEGFP to the hyphal tip, with the signal strength declining towards the back, but sometimes still visible up to 10 mm from the tip (figure 21, A). The signal intensity was not the same at different branches of the same mycelium, sometimes missing entirely.

In single-plane images, localization to the outer, cortical zone of the hyphal tip could be observed (figure 21, B).

MEN orthologs are not essential for growth but play a role in sporulation

Given the analogous localization patterns of AgLte1 and AgTem1 and the high sequence identity of MEN orthologs in general, an analogous cellular function of MEN components in *A. gossypii* is plausible. In order to clarify whether the *A. gossypii* orthologs of this pathway fulfill similar roles, we created single-gene deletions for putative core components and peripheral contributors AgTEM1, AgCDC15, AgDBF2/DBF20, AgMOB1, AgLTE1, AgKIN4/FRK1 and AgKEL1/KEL2. Unexpectedly, viable, homokaryotic null mutants could be generated for all selected MEN related orthologs in *A. gossypii*. We then proceeded to conduct routine macroscopic

growth assays. At the optimal growth temperature of 30°C, all strains exhibited radial growth speeds similar to wt, except *Agkin4/frk1Δ* and *Agkel1/kel2Δ* mutants, which (expressed as radial colony growth) grew approximately 10% slower (figure 22, A). Some mild growth impairments could be observed in all mutants at non-optimal temperatures, notably including an increased sensitivity to low temperatures in *Agkte1Δ* mycelia. Mycelial morphology at the edge of colonies was normal for all strains at 30°C, except for slight irregularities observed in *Agkin4/frk1Δ* mutants (figure 22, D). Circular areas of defined size (6 cm<sup>2</sup>) were excised from the center of 6 day old colonies, and checked for spore content and weight of mycelium. The mutants *Agtem1Δ*, *Agcdc15Δ*,

**Figure 22: Macroscopic development of MEN mutants.** (A) Radial growth speeds of mutants at 30°C, 20°C and 37°C after 5 days. Values represent the mean of 2 or 3 separate measurements done with individual strains, which are indicated by thin horizontal bars. (C) Samples taken from spore preparations of inner 3 cm of 6 day old colonies. Scale bar depicts 0.1 mm. (D) Edges of 6 day old colonies at 30°C. Scale bar depicts 0.1 mm.

*Agdbf2/dbf20Δ* and *Agmob1Δ* were shown to have severe sporulation deficiencies (figure 22, C). The same strains also accounted for less mass (figure 22, B) than wt, suggesting defects in later developmental stages. To gain understanding of these sporulation deficiencies, we transferred 1 day old mycelia to nutrient deprived liquid medium cultures in an attempt to trigger the sporulation program at a young stage. Differences between wt and *Agtem1Δ* samples were observed within 48 hours of switching to low nutrients. Sporangia in mutant strains could not develop properly. This was likely caused by some defect in septation, as regular segmentation of bloating hyphae was not observed frequently in mutants (figure 23). The few spores observed to start forming after 72 hours in *Agtem1Δ* developed in non-compartmentalized sections of the hyphae (figure 23, B). These observations are in agreement to chitin stainings of *Agmob1Δ* mutant mycelia (using Calcofluor White), where well formed mature septa can only seldomly be seen (figure 24).

### Effect of deletion of MEN orthologs in *A. gossypii* on anaphase nuclear dynamics

Because MEN null mutants such as *Sctem1Δ* in *S. cerevisiae* fail to exit mitosis and arrest with elongated spindles (Shirayama *et al.*, 1994), we measured anaphase dynamics of dividing nuclei in *Agtem1Δ* *AgH4-GFP* hyphae by determining the diameter of the H4-GFP-signal in 1 minute intervals over the course of half an hour. No delay of events

could be detected in *Agtem1Δ* mutants (figure 25, B), compared to wt (figure 25, A): Maximum spindle length (typically between 7 and 8  $\mu\text{m}$ ), duration of anaphase (typically 9 minutes) and time of spindle breakdown (indicated by independent oscillation movements of post-anaphase nuclei, typically around 15 minutes after onset of anaphase, but subject to variation) were all shown to be like wild-type.

### The distribution of nuclei in growing hyphae upon deletion of putative MEN orthologs in *A. gossypii*

To aid in making assertions on mitotic activity in growing hyphae, we calculated the density of nuclei (*AgH4-yEGFP* signals) in different regions which were defined by the distance from the growing tip. This spatial distinction arose from the assumption that mitotic activity may be affected in mutants dependent on the position within the hyphae, given the restricted localization of *AgLte1-yEGFP* to the foremost 10-15  $\mu\text{m}$  of hyphal tips. Measurements showed a slight increase in distance between nuclei towards the backward regions of growing wild-type hyphae (figure 26). No significant differences to wild-type could be detected in *Agtem1Δ* or *Agdbf2/dbf20Δ* mutant strains. The overall average distance throughout all defined areas was calculated to be  $4.47 \pm 2.06 \mu\text{m}$  (1 SD, N = 193) for wild-type,  $4.44 \pm 2.82 \mu\text{m}$  (1 SD, N = 173) for *Agtem1Δ* and  $4.58 \pm 2.65 \mu\text{m}$  (1 SD, N = 199) for *Agdbf2/dbf20Δ*.

**Figure 23: Sporangia and developing spores in *Agtem1Δ*.** DIC images of hyphae after (A) 48 hours and (B) 72 hours in 1:4 diluted AFM liquid cultures. Blue arrowheads indicate mature septa. Red arrowheads indicate developing spores. Scale bars depict 10  $\mu\text{m}$ .

**Figure 24: Septum staining in *Agmob1Δ*.** Calcofluor White stainings visualizing chitin-harboring septa in cells taken from o/n liquid AFM cultures inoculated with pieces of mycelium from edge of plate colonies. Chitin stains show at growing and emerging hyphal tips as well as at septa. Yellow arrowheads indicate chitin staining at polarized growth tip. Blue arrowheads indicate chitin staining at septa. Scale bar depicts 10  $\mu$ m.

### Quantifying nuclear division cycle stages in MEN ortholog mutants *Agtem1Δ*, *Agcdc15Δ*, *Agdbf2/dbf20Δ* and *Aglte1Δ*

Because nuclear density in the areas observed could potentially be maintained in cells with decreased mitotic frequency simply by distributing nuclei towards the front, a more detailed look at the mitotic cycle was necessary. We deleted *AgTEM1*, *AgCDC15*, *AgDBF2/DBF20* and *AgLTE1* in an *AgH4-GFP AgTub4-YFP* background, so as to be able to differentiate whether individual nuclei were in interphase, metaphase or anaphase. We then inspected more than 300 nuclei for each strain,

only taking into consideration fast growing hyphae which had recently undergone tipsplitting (detailed description of experiment in materials and methods section). In the wt reference strain, we found 86.6% interphase, 11.7% metaphase and 1.7% anaphase nuclei. Although these numbers are similar to results obtained for wild-type in similar experimental setups (Helfer and Gladfelter, 2006: 80%, 16% and 3%; Claudia Lang, doctoral thesis: 92%, 6% and 2%), the method may not detect all anaphase nuclei, mistaking them for interphase nuclei due to nuclear bypassing and crowded hyphae. MEN ortholog mutants *Agtem1Δ*, *Agcdc15Δ*, *Agdbf2/dbf20Δ* were shown to have increased fractions of metaphase

**Figure 25: Anaphase dynamics in *Agtem1 $\Delta$*  mutant.** Overlay of multiple measurements of AgH4-GFP signal diameter of mitotic nuclei in wild-type reference strain (*AgH4-GFP*) (A) and *Agtem1 $\Delta$*  (B) hyphae. Overlay achieved by translation along x-axis (synchronization of data, no scaling adjustments). (C) Overlay of wt (blue) and *Agtem1 $\Delta$*  (red) measurements. Visual approximation of typical anaphase event provided by black curve.

**Figure 26: Distribution of nuclei in MEN mutants.** Mean distances between nuclei in defined regions of hyphae (illustrated below) in wild-type reference strain (*AgH4-GFP*) and MEN mutants.

**Figure 27: Occurrence of metaphase nuclei in MEN mutants.** (A) Percentages of total counted nuclei found to be in different nuclear division cycle stages in wild-type reference strain (*AgH4-GFP AgTub4-YFP*) and MEN mutants. (B) Percentages of nuclei within individual hyphae found to be in metaphase. Error bars represent one standard deviation.

**Figure 28: Positional distribution of metaphase nuclei within hyphae.** (A) Distance of individual identified metaphase nuclei from the tip-splitting fork site in wild-type reference strain (*AgH4-GFP AgTub4-YFP*) and MEN mutants. Dots represent metaphase nuclei, grey horizontal lines represent the tip of the hypha. Measurements are sorted along the x-axis by length of hyphae after the fork site. (B) Mean distance of metaphase nuclei from the hyphal tip in wild-type reference strain (*AgH4-GFP AgTub4-YFP*) and MEN mutants. Whisker plot depicts 25th percentiles.

nuclei of approximately 27-30% (Figure 27, A). In *Agltel1Δ* cells, 17% of nuclei were found to be in metaphase. In order to demonstrate the large variation observed within strains, we also made separate percentage calculations for each individual hypha (as opposed to pooling all nuclei and calculating the overall mean), and then calculated the mean and SD from these values. In the resulting representation (figure 27, B), the mild enrichment of metaphase nuclei observed in the *Agltel1Δ* strain (17% versus 11.7% in wild-type) is almost reduced to wild-type values by this alternative form of data processing.

### Spatial occurrence of metaphase nuclei in *Agtem1Δ*

To investigate the possibility of a spatial dependence of these observations, we measured the position of nuclei identified as being in metaphase in selected mutants, relative to the hyphal tip and the fork site. We plotted these coordinates, but could not recognize any pattern. Occurrence of metaphase nuclei was seemingly well dispersed and not found to be enriched in any defined area in wildtype, *Agtem1Δ*, or *Agltel1Δ* (Figure 28, A). No significant increase or decrease of metaphase nuclei was detected towards the hyphal tip in any of the strains, including *Agltel1Δ*, nor was there a detectable enrichment around the fork site, where septa are laid down in fast growing hyphae (Kaufmann and Philippsen, 2009), and entry into mitosis is therefore expected to be stimulated (Helfer and Gladfelter, 2006). These findings were also made apparent in whisker plots of the same data, representing distances of metaphase nuclei from the growing tip (Figure 28, B): Distribution of metaphase nuclei from tip of the cell is very similar between wild-type, *Agtem1Δ*, and *Agltel1Δ*.

### *AgCdc14* release dynamics in *Agcdc15Δ* mutants

Given that an immediate consequence of MEN signalling in *S. cerevisiae* is sustained release of *ScCdc14* during later stages of anaphase, experiments were conducted to clarify the role of the *A. gossypii* orthologs in localization patterns of *AgCdc14*. To be able to detect minor changes in

release dynamics, we introduced *AgPds1*-mCherry into our *AgCdc14*-GFP background strain. *ScPds1*, or securin, is an inhibitor of separase and is degraded in an APC-dependent manner, triggering the onset of anaphase (Cohen-Fix *et al.*, 1996). The intention of including this marker was to provide an additional visual cue (the disappearance of *AgPds1*-Cherry) for the metaphase/anaphase transition as a temporal reference to base the timings of our observations of *AgCdc14*-yEGFP on. Isolated *AgPds1*-Cherry *AgCdc14*-GFP homokaryotic strains were viable and thus deemed functional. The ORF of *AgCDC15* was deleted in this strain, and time-lapse image series of both mCherry and GFP signals were acquired (Figure 29). *AgCdc14* dynamics were shown to be very similar to what was observed in wild-type. Seemingly coincidental with the first signs of *AgPds1* degradation, *AgCdc14* would start to become visible at the SPBs, indicating initial release from the nucleolus. Around the time *AgPds1* reached baseline levels, *AgCdc14* release was to full extent. No return of *AgPds1* could be made out in post-mitotic nuclei, where *AgCdc14* was resequenced in the nucleoli. In order to provide quantitative data to these anecdotal observations, we measured various features of these dividing nuclei (full description in materials and methods): To quantify sequestered *Cdc14*, we calculated the number of high intensity yEGFP-channel pixels within fixed mitotic areas (figure 29, yellow polygonal shape in left column). For *AgPds1* levels, we measured mCherry signals at the center of nuclei (figure 29, circular area in middle column). We also measured elongation of the mitotic spindle using the SPB signal of *AgCdc14* which was always visible for the entire duration of anaphase. The measurements, although quite noisy (which was countered by overlaying the data), confirmed our prior observations (Figure 30). No significant differences were found between *Agcdc15Δ* and wild-type nuclei concerning the timing and sequence of such events as *AgPds1* degradation, *AgCdc14* release, spindle elongation or *AgCdc14* resequstration.

**Figure 29: *AgPds1* as a visual marker for initiation of anaphase.** Time-lapse series of *Agcdc15Δ* *AgCdc14*-GFP *AgPds1*-mCherry nucleus undergoing mitosis. Yellow polygons demonstrate areas measured to generate data shown in next figure. 1 minute time interval. Scale bar depicts 1  $\mu$ m.

**Figure 30: Dynamics of AgCdc14 release in *Agcdc15Δ* mutant.** Measurement details in materials and methods section. Different colors indicate individual experiments. Overlay of measurements by translation along x-axis (synchronisation of data between experiments) and scaling along y-axis (mapping to comparable ranges). Spindle lengths (top panel) were not scaled vertically so units ( $\mu\text{m}$ ) were retained. Other (signal intensity) measurements in arbitrary units due to scaling.

## Discussion

On the amino acid level, *A. gossypii* carries the entire set of genes constituting the MEN in *S. cerevisiae*. High sequence identity values calculated for most core components of the signalling cascade and the identification of all predicted functional domains both speak in favor of a conserved role within the hyphae of *A. gossypii*.

This perception is enforced by the similarities in localization patterns observed for *AgTem1* (at the SPBs) and *AgLte1* (at the hyphal cortex). However, important differences exist. Notably, *AgTem1* localizes to *both* SPBs of dividing nuclei, with no signs of signal fluctuation during the course of the nuclear division cycle. The asymmetrical pattern seen in *S. cerevisiae*, with *ScTem1* localizing to the dSPB has been the subject of recent studies. Consequences of targeting *ScTem1* to both SPBs could not be detected (Fraschini *et al.*, 2006). The localization of *ScTem1* is determined by the *ScBfa1-ScBub2* complex (Pereira *et al.*, 2000; Monje-Casas and Amon, 2009). *ScBfa1-ScBub2* on the other hand seems to depend upon factors such as formins (Monje-Casas and Amon, 2009) and even *ScLte1*, which was shown to be crucial for correct polarity cap position (Geymonat *et al.*, 2009). This suggests that the contribution of *ScLte1* to mitotic exit may stem from its role in cell polarization. In this light, the localizations observed in *A. gossypii* could be interpreted as follows: *AgLte1* likely plays a role in cell polarity, however it appears that this polarity cannot and is not inherited to the nuclei. The gradient observed, determining the anterior part of the hypha, is probably of to large a scale to be able to reliably differentiate between opposite SPBs of a highly motile, dividing nucleus. The symmetry of *AgTem1* localization does not necessarily exclude a role of the protein in nuclear cycle regulation, however it does suggest that such a control system involving *AgTem1* would likely function completely oblivious to the polarity of the cell, the sensing of which is seen as a defining feature of the MEN in *S. cerevisiae*.

The discovery that deletion mutants of MEN homologs in *A. gossypii* are viable and grow at wt-like speeds on plates is in strong contrast to the

situation in budding yeast, where MEN signalling is essential for viability. The deficiencies of these mutants in spore production hint at a conserved role in sporulation and it is tempting to make a connection to the role of the MEN in spore formation in budding yeast. There, MEN components have been shown to play a role in and disassembly of meiosis II spindles, most likely by maintenance and shuttling of *ScCdc14* release similar to mitosis. Furthermore, *ScCdc15* is crucial for normal prospore membrane formation and nuclear capture (Pablo-Hernando *et al.*, 2007). These events are initiated at the SPBs. It therefore plausible that the reduction in numbers of spores observed in the *A. gossypii* MEN homolog mutants could be traced back to developmental malfunctions such as flawed spore wall nucleation. However the few spores produced all had normal morphology, suggesting that spore development per se was unaffected, and that more likely the initiation of sporulation itself was disturbed. Looking at maturing hyphae, it became evident that the morphology of sporangia themselves were abnormal, with septation impaired. MEN components have been shown to localize to the bud neck and, more specifically, *ScTem1*, *ScCdc15*, *ScDbf20* and *ScDbf2* have been shown to be important for cytokinesis and controlling the re-polarization of the actin cytoskeleton (Corbett *et al.*, 2006). Sporulation deficiencies have also been observed in mutants of septation factors (Kaufmann, PhD thesis). What also stood out was the same common sporulation phenotype across all *Agtem1Δ*, *Agcdc15Δ*, *Agdbf2/dbf20Δ* and *Agmob1Δ* strains. This can be understood as an indication that the core signalling cascade as described in yeast may be intact in *A. gossypii*.

The investigation of the nuclei in *A. gossypii* MEN homolog mutants revealed great differences compared to MEN mutants in *S. cerevisiae*. Wild-type-like anaphase dynamics and timing of spindle breakdown in our mutant strains suggest a major deviation from the role established in budding yeast. Apparently, MEN homologs play no part in orchestrating the final steps in mitosis. Also, judging by nuclear density along the hyphae, no effect on

the nuclear division cycle as a whole could be made out either: wild-type values for nuclear density, combined with perfectly healthy growth speeds suggest that overall frequency of mitosis in these mutants is unperturbed. However, upon a more detailed look at different nuclear division cycle stages, a partial arrest in metaphase was discovered in the *Agtem1Δ*, *Agcdc15Δ*, *Agdbf2/dbf20Δ* and *Agmob1Δ* strains (once again suggesting that the core kinase cascade of the pathway is conserved). This is insofar surprising as it suggests a crucial role of these MEN signalling cascade homologs prior to anaphase. What could this function be? A healthy guess, at least timing-wise, would be triggering the degradation of *AgPds1*, an anaphase inhibitor (Gladfelter *et al.*, 2007). On the inside of the *S. cerevisiae* nucleus, the so-called spindle checkpoint inhibits the degradation of *ScPds1* by complexing *ScCdc20* until kinetochores are properly attached to MTs. Perhaps a similar system exists in *A. gossypii* involving MEN homologs ensuring the proper attachment of cMTs to the outer plaque of mitotic SPBs?

Or perhaps the MEN homologs directly mediate cytoplasmic pulling forces and the metaphase delay in mutants simply reflects the inability to efficiently elongate the mitotic spindle by internal forces only. In any case, the effect observed was not dependent on position of the nucleus within the hypha, meaning that the MEN homologs in *A. gossypii* do not help promoting (or allowing) mitosis close to growing tips for example. Anyhow, due to the observed timing of events (with *AgCdc14* only fully released during anaphase) it seems unlikely that the MEN homologs would execute such a function via the *AgCdc14* phosphatase.

What was further made evident in this experiment was the ability of nuclei to correct for prolonged metaphase by reducing the time spent in interphase. Apparently there is a regulatory system in place adjusting the frequency of mitosis in order to maintain an ideal density of nuclei in a variety of circumstances. This likely comes in handy throughout different stages of the life cycle of *A. gossypii*, when cells have to adapt to altering growth speeds and morphology as well as fractioning of the nuclear population by branching and tip-splitting. The simplest thinkable mechanism would be an instable factor diffusing from nuclei which

can inhibit cell cycle progression of neighbouring nuclei.

Importantly, no role in *AgCdc14* release could be detected for the MEN homolog *AgCdc15*. This further minimizes the possibility that the partial metaphase arrest observed in MEN homolog mutants is mediated via downstream *AgCdc14*, and likely marks a decoupling of the conserved signalling cascade from this important regulatory function first described in budding yeast. This does not rule out a regulatory function towards cytoplasmic *AgCdc14*.

This experiment also provided further important information on the nature of the partial metaphase seen in MEN homolog mutants in terms of time of action. The function involved in this arrest clearly precedes *AgPds1* degradation, because no delay in spindle elongation was observed in nuclei where *AgPds1* degradation was successfully triggered, when comparing our mutant to wild-type.

Having gathered evidence against a role of MEN homologs in *AgCdc14* release, it will be interesting to see how the remaining system has adapted, or more precisely, what part FEAR homologs play in this important step of the nuclear division cycle.

## CHAPTER III

## CHAPTER III: FEAR HOMOLOGS IN *ASHBYA GOSSYPHII*

### Introduction

The discovery that MEN homologs in *A. gossypii* do not contribute to *AgCdc14* release or M-phase to G1 transition raises the question whether the entire underlying regulatory machinery known from *S. cerevisiae* is uncoupled from these tasks, or if control over *AgCdc14* activation has been bestowed upon a network made up of homologs of the FEAR pathway. Latter is certainly an exciting possibility in the light of the predictions discussed previously (Bosl and Li, 2005), however the need for the entire pathway as described for budding yeast is not completely self-evident in a multinucleate environment.

This chapter discusses investigations into the necessity of FEAR orthologs for successful progression through the nuclear division cycle in *A. gossypii*. As in the previous chapter, special

attention is given to effects of mutations of the system on mitotic behaviour and *AgCdc14* release. One possible consequence of the lack of contribution of MEN homologs to *AgCdc14* release may be a detectable lack of robustness towards disruption of the putative FEAR regulatory pathway. If FEAR homologs were indeed discovered to play a role in *AgCdc14* release, then such a decrease in functional redundancy may manifest itself in reduced viability of FEAR homolog deletion mutants, compared to *S. cerevisiae* counterparts. In budding yeast, deletion mutants of the FEAR pathway are all viable, with the exception of separase, and in synchronized experimental setups deletion or over-expression mutants will display temporal shifts in events such as *ScCdc14* release (figure 31) or *ScClb2*-Cdk downregulation.

**Figure 31: FEAR phenotypes.** (A) Premature release of ScCdc14 in synchronized *Sccdc55Δ* cells (adapted from Queralt *et al.*, 2006). (C) Delayed and reduced release of ScCdc14 in pheromone synchronized *Scmad1Δ Scslk19Δ* cells (adapted from Stegmeier *et al.*, 2002). (D) Delayed release of ScCdc14 in pheromone synchronized *Sczds1Δ* cells (adapted from Queralt and Uhlmann, 2008). (E) Delayed release of ScCdc14 in pheromone synchronized, galactose induced *Scmad1Δ* GAL1-ScFOB1 cells (adapted from Stegmeier *et al.*, 2004).

## Materials and Methods

### General

*A. gossypii* media, growth conditions, transformation, bioinformatic analysis, microscopy, measurements and strain verifications are as described in the previous chapters. All plasmids and strains used are listed in supplemental tables 5 and 6.

## Results

### Conservation of *S. cerevisiae* FEAR genes in *A. gossypii*

All budding yeast genes described in literature to be somehow involved in FEAR signalling were identified as annotated, syntenic ORFs in the *A. gossypii* genome (table 3). Relatively low amino acid sequence identity values ( $\leq 50\%$ ) were calculated for all *A. gossypii* FEAR orthologs, except for the putative subunits of the PP2A phosphatase complex (*AgCDC55*, *AgPPH21*/*PPH22* and *AgTPD3*), which had IDs ranging from 78% to 86%. The number of predicted Cdk phosphorylation motifs predicted was in only roughly within the same range for homologs, with the most notable difference being in *AgSLK19* (6 motifs in *A. gossypii* versus 3 in *S. cerevisiae*)

In a more detailed look at the amino acid sequence, we found all domains predicted for the *S. cerevisiae* genes to be predicted for the *A. gossypii* orthologs as well (figure 32). Such a high degree of homology however was not restricted to predicted domains. Within *AgFob1* and *AgSlk19* for example, there were found to be highly conserved stretches located outside of identified domains, likely representing domains of yet to be clarified function themselves.

### Effect of *AgCDC55* deletion on *AgCdc14* sequestration and growth in *A. gossypii*

Given the apparent lack of function of MEN orthologs in *AgCdc14* regulation in *A. gossypii*, we were curious to see to what extent FEAR orthologs play a role in this crucial task and set out to create a complete deletion collection of all orthologs of proposed FEAR network components. In a preliminary study, it could be shown that the putative FEAR ortholog *AgCdc55* was essential for the viability of young mycelia, as *Agcdc55Δ* mutants ceased growth, showed swelling and then lysed after approximately 24 hours (Valentin Tilloy, summer internship, supplemental figure 3). We then carried out the deletion of the *AgCDC55* ORF in a *AgCdc14*-yEGFP background strain and assessed GFP localization prior to lysis of the cells. In *Agcdc55Δ*, the *AgCdc14*-yEGFP localization pattern was at all times and in all nuclei reminiscent of the unsequestered signals we observed for anaphase nuclei in wild-type: The fusion protein exhibited a low intensity signal in what appears to be the nucleoplasm and bright foci at what we assume to be the SPBs (figure 33, A). Thus it seems that *AgCdc14*-yEGFP is constantly in a released state in these mutants.

Judging by the *AgCdc14*-yEGFP signals, the number of nuclei is strongly reduced in these mutants, compared to wild-type cells. Of all nuclei

<i>A. gossypii</i> ortholog					<i>S. cerevisiae</i> 1st homolog					<i>S. cerevisiae</i> 2nd homolog

observed, almost all appeared to be in interphase, and only one instance of mitosis was captured by imaging (figure 33, B). In this incidence, it seemed that anaphase spindle elongation was not affected (in terms of duration and attained length), although it was not clear, due to lack of movement, if the nuclei could properly separate after maximum elongation was reached. Quite often, nuclei were observed that had remained connected by a continuous nucleoplasm, visible as a faint and mostly crooked *AgCdc14*-yEGFP signal (figure 33, A, yellow arrowhead). In the mutant strain, nuclei

were also observed to be much larger than in wild-type, with diameters of more than 5  $\mu\text{m}$  measured in most cases, making nuclei too large to properly pass through the hyphae in some places.

#### Effect of *AgSPO12/BNS1* deletion on mitosis and growth in *A. gossypii*

A notable phenotype discovered in our deletion collection is that of *Agspo12/bns1* $\Delta$ . We deleted the *AgSPO12/BNS1* ORF in an *AgH4*-GFP to be able to monitor nuclear behaviour. Mutants would

**Figure 33: AgCdc14 release in *Agcdc55Δ* mutant.** (A) AgCdc14-yEGFP signal in 18 hour old *Agcdc55Δ* mycelium. Maximum intensity projection of 11 planes with a Z-distance of 0.5 μm. Scale bar depicts 10 μm. (B) AgCdc14-yEGFP signal in dividing nucleus of hour old *Agcdc55Δ* mycelium. Images taken 17 and 18 minutes apart, respectively. Scale bar depicts 1 μm. (C) AgCdc14-yEGFP signal in 18 hour old wild-type reference strain (AgCdc14-GFP). Maximum intensity projection of 11 planes with a Z-distance of 0.5 μm. Scale bar depicts 10 μm.

often cease growth at the germ bubble stage and occasionally could form primary germ tubes. In such cells we were able to monitor nuclei over a period of up to 14 hours (figure 34). Nuclei were in motion during the entire duration of the experiment, but mitosis was strongly impaired, as shown by time lapse imaging (figure 34, nucleus marked by yellow arrowhead is discussed in the following). Separation of DNA did not follow regular dynamics. Beginning and end of mitosis could not be identified and DNA was seemingly separated in multiple attempts over the course of approximately 4-5 hours. In first step, only part of the DNA is moved, creating 2 fractions with differing signal intensities (green arrowheads). In a second step, taking roughly 2 hours, more DNA is transferred, resulting in two equally bright nuclei. The nucleus located in the germ bubble exhibits more wild-type-like behaviour. This may be due to residual *AgSpo12/Bns1* protein retained in this area from the heterokaryotic mycelium the spores originate from.

### Macroscopic phenotypes of non-lethal FEAR ortholog mutants

Not all FEAR ortholog disruptions had such severe effects. Deletions of *AgSLK19*, *AgFOB1* and *AgZDS1/ZDS2* were shown to be non-lethal. *Agslk19Δ* and *Agzds1/zds2Δ* however showed mild and strong growth phenotypes respectively at all tested temperatures (figure 35, A). *Agfob1Δ* did not show any sign of radial growth impairment. The reduction of radial growth speed in *Agslk19Δ* and *Agzds1/zds2Δ* correlated with decreased weight of the inner part of the colony (figure 35, B). Interestingly, these impairments were accompanied by a reduction of spore production in the *Agslk19Δ* (figure 35, C), but not in the *Agzds1/zds2Δ* strain. This sporulation defect was clear, but not as pronounced as observed in MEN mutants (Chapter 2, Figure 22, C). In addition, *Agslk19Δ* mycelia displayed frayed growth edges, with a visibly lower density of hyphae in the frontmost 0.5 mm of growing colonies (figure 35, D).

**Figure 34: Behaviour of nuclei in *Agspo12/bns1Δ* mutant.** Time lapse series of AgH4-GFP in *Agspo12/bns1Δ* germling. 25 minute time interval beginning at 8 hours after spreading of spores. Scale bar depicts 10  $\mu\text{m}$ .

### Effect of *AgSLK19* deletion on mitosis in *A. gossypii*

We were interested to see if the observed growth defects were in connection with any mitotic deficiencies and investigated the density of nuclei (AgH4-yEGFP signals) in pre-defined regions of post-tipsplitting hyphae as described in the previous chapter. The measurements show a clear increase in inter-nuclear distance in *Agslk19Δ* (figure 36). This effect was not limited to a specific region of the hyphae, but did seem slightly stronger towards the tip. This however is likely only due to large variation as a consequence of relatively small sample sizes (in turn being the cost of spatial resolution). Overall average distance in *Agslk19Δ*

was calculated to be  $11.34 \pm 5.43 \mu\text{m}$  (1 SD, N = 111), more than double the values determined to be  $4.47 \pm 2.06 \mu\text{m}$  (1 SD, N = 193) for wild-type or  $4.34 \pm 2.25 \mu\text{m}$  (1 SD, N = 185) for *Agfob1Δ*.

### Effect of *AgSLK19* on *AgCdc14*-yEGFP release

To investigate whether the decreased mitotic activity detected in *Agslk19Δ* was caused by compromised *AgCdc14* regulation, we repeated the disruption in *AgCdc14*-yEGFP cells. *AgCdc14*-yEGFP sequestration and release seemed intact, with typical wild-type like localization patterns throughout anaphase (figure 37), although no precise quantification was undertaken.

**Figure 35: Macroscopic development of non-lethal FEAR mutants.** (A) Radial growth speeds of mutants at 30°C, 20°C and 37°C after 5 days. Values represent the mean of 2 or 3 separate measurements done with individual strains, which are indicated by thin horizontal bars. (B) Weights of the inner 3 cm of mycelium taken for spore isolation from the growth assay plates. Mean values of 2 or 3 separate measurements, indicated by thin horizontal bars. (C) Samples taken from spore preparations of inner 3 cm of 6 day old colonies. Scale bar depicts 0.1 mm. (D) Edges of 6 day old colonies. Scale bar depicts 0.1 mm.

**Figure 37: *AgCdc14* release in *Agslk19Δ* mutant.** Time lapse series of *AgCdc14*-yEGFP in mature *Agslk19Δ* mycelium. 1 minute time interval. Scale bar depicts 1 μm.

**Figure 38: Nuclei and SPBs in *Agslk19Δ* mutant.** Channel merge of *AgTub4*-YFP (red) and *AgH4*-GFP (green) images of fast growing (as indicated by tip-splitting) hyphae on TL-slides. Yellow arrowhead indicates nucleus with no SPB. Red arrowhead indicates nucleus with 3 SPBs. Blue arrowheads indicate lone SPBs attached to no nucleus or nuclear fragment. Scale bars depict 10 μm.

## Detailed look at nuclear division cycle stages in viable FEAR ortholog mutants

In *S. cerevisiae* FEAR and MEN share functional overlap in terms of their roles in *ScCdc14* regulation. We repeated the experiment used in Chapter 2 to detect enrichment of metaphase nuclei with the FEAR ortholog mutants *Agslk19Δ*, *Agfob1Δ* and

*Agzds1/zds2Δ* in order to find out if the functions indicated by partial metaphase arrest were also shared by these putative FEAR components.

Measurements as performed in the MEN ortholog mutants were not possible in *Agslk19Δ*. Upon inspection of *AgTub4*-YFP in the strains generated for the experiment, it became apparent that the nuclei in these mutants could not be categorized

**Figure 39: Occurrence of metaphase nuclei in non-lethal FEAR mutants.** (A) Percentages of total counted nuclei found to be in different nuclear division cycle stages in wild-type reference strain (*AgH4-GFP AgTub4-YFP*) and FEAR mutants. (B) Percentages of nuclei within individual hyphae found to be in metaphase. Error bars represent one standard deviation.

in a fashion comparable to the data collected previously. Nuclei (or *AgH4-GFP* patches) could often be observed which had three (figure 38, red arrowhead) or no SPBs (figure 38, yellow arrowhead). Also, there seemed to be detached SPBs within the cytoplasm, not stably connected to any nuclei at all, or connected to what appears to be fragments of nuclei (figure 38, blue arrowheads). We also noticed morphological abnormalities of nuclei (aberrant shapes of *AgH4-GFP*), something that had evaded our attention in our previous studies of nuclear density in *Agslk19*Δ mutants.

For *Agfob1*Δ and *Agzds1/zds2*Δ mutants, conventional categorizations of nuclei could successfully be made using the combination of *AgH4-GFP* and *AgTub4-YFP* signals.

Quantifications showed that no significant enrichment of any stage of the nuclear division cycle could be detected in these strains (figure 39, A). Alternative data processing as described for the analogous experiment in Chapter 2 uncovered no apparent change in tendencies (figure 39, B): Percentage values of metaphase nuclei determined were  $12.7 \pm 11.1$  % (1 SD, N = 358) for wild-type,  $12.7 \pm 9.9$  % (1 SD, N = 347) for *Agfob1*Δ and  $8.5 \pm 7.0$  % (1 SD, N = 221) for *Agzds1/zds2*Δ. Lower sample numbers were generated for *Agzds1/zds2*Δ mutants due to reduced capability to undergo tipsplitting in this particular experimental setup (a prerequisite for consideration, see materials and methods). This may be caused by the described reduction in growth speed.

## Discussion

The results from the experiments with MEN homologs led to the question what role FEAR components may have in regulating anaphase events. Has the entire network in charge of bringing about exit from mitosis been reduced to a minimal set of genes comprised of FEAR homologs?

*A. gossypii* was found to have orthologs to all genes associated with FEAR in *S. cerevisiae*. Sequence identity values are slightly lower on average compared to the MEN homologs, and only components of the putative PP2A<sup>AgCdc55</sup> complex are highly conserved. Nevertheless, all predicted functional domains are present.

Deletion of *AgCDC55* was found to be lethal and provoked a striking phenotype concerning *AgCdc14*-yEGF release. In these cells, which halted all growth and lysed within 24 hours, *AgCdc14* was found to be in permanent released form. This is in contrast to *Sccdc55Δ* cells which show premature release of *ScCdc14*, but successful, albeit delayed return to the nucleolus. This discrepancy seems to suggest that in *A. gossypii*, *AgCdc55* downregulation might be sufficient for full, sustained release and thus may even belong to a sole pathway causing *AgCdc14* activation.

What exactly leads to the death of *Agcdc55Δ* cells is not entirely clear. Despite permanent activation of *AgCdc14*, mitosis is not entirely abolished, however, nuclei expand to a remarkable size, possibly suggesting endo-reduplication, which could lead to all kinds of dosage dependent effects. Such drastic perturbations may also be detected and trigger apoptosis. Another cause for these aberrant nuclei could also be that *AgCdc14* regulates nuclear membrane expansion during anaphase. *AgCdc14* being constantly active throughout interphase would therefore lead to bloated nuclei. Or perhaps the observations rather reflect other effects of constantly low Cdk activity due to an antagonistic effect of *AgCdc14*.

Another drastic outcome was observed in *Agspo12/bns1Δ* mutants. Given the putative role as an inducer of *AgCdc14* activation, the apparent failure to undergo nuclear abscission (and thus successfully exit mitosis) in these cells may well stem from failed release of the phosphatase. The inability

to fully divide may be due to problems in rDNA segregation (which is strongly linked to *ScCdc14* effector function). A high degree of conservation (five identical surrounding amino acids) of the phosphorylation site at S118 in *ScSpo12*, which is essential for function within FEAR (Tomson *et al.*, 2009), additionally speaks in favor of a conserved role of *AgSpo12/Bns1* in *AgCdc14* regulation. The phenotype observed may stand in contrast to behaviour observed in *Agcdc14Δ* mutants, however full deletion of *AgCDC14* may also bring about other defects which mask late anaphase deficiencies. In this sense, perhaps the *Agspo12/bns1Δ* better reflects a lack of activated *AgCdc14* during anaphase. To investigate sequestration specifically, we additionally constructed a *Agspo12/bns1Δ* strain carrying *AgCdc14*-yEGFP and could only see the phosphatase in its sequestered form (supplemental figure 6). Unfortunately however, these cells displayed even less viability than *Agspo12/bns1Δ* H4-GFP cells, with no germ tubes forming at all and no mitotic events successfully recorded. This may hint at compromised functionality of the *AgCdc14*-yEGFP construct.

*Agfob1Δ* mutants did not show any mitotic or developmental phenotype at all. This is similar to *S. cerevisiae* where *ScFob1* deletion shows no phenotype in synchronized cells. Possibly, *AgFob1* also only has a minor role as in *AgCdc14* regulation, which, as in budding yeast, only becomes apparent in perturbed cell cycle progression.

*Agzds1/zds2Δ* cells display radial growth speed deficiencies, but have no apparent trouble proceeding through mitosis. Because *ScZds1* is known to be potentially involved in many different areas (hence the alias “zillion different screens”) ranging from polarity (Zanelli and Valentini, 2005), sister chromatid cohesion (Heo *et al.*, 1999), chromatin silencing (Roy and Runge, 2000) or cell wall integrity signalling (Griffioen *et al.*, 2003), the causes for the observed reduced growth speeds cannot be conclusively deduced from our experiments. Concerning a possible function in FEAR, one may have anticipated at least a mild phenotype in nuclear division cycle progression, since the *Agcdc55Δ* mutant shows such clear

malfunctioning and *AgZds1/Zds2* is a potential upstream inhibitor of the PP2A. In such a case we would have expected deficiencies down the lines of *Agspo12/bns1Δ*. As it seems however, *AgZds1/Zds2* may not be involved in PP2A<sup>AgCdc55</sup> downregulation. Perhaps in *A. gossypii*, PP2A<sup>AgCdc55</sup> is more directly inhibited by *AgEsp1-AgSlk19* activity, and the inclusion of the seemingly polyvalent *ScZds1* and *ScZds2* in the FEAR pathway in budding yeast reflects a timing of polarity or cell-wall related events to occur during anaphase, a coordination that *A. gossypii* can do without.

*Agslk19Δ* mutants are viable, but have shown nuclear phenotypes reminiscent of the *Agspo12/bns1Δ* phenotype, however not quite as lethal. Mitosis seems to be heavily disturbed and hyphae carry only about half the nuclei that wild-type do. *AgCdc14* appears to be released successfully, however we did not conduct an experiment to see

if there is a delay in metaphase/anaphase transition, and cannot rule out a shift of events relative to *AgPds1* degradation. Possibly, what we see is rather a result of malfunction of separase due to a loss of interaction with *AgSlk19*. This would fit more nicely to the observations of more than two SPBs on some nuclei, which for example could be due to *AgEsp1* triggering *AgCdc14* release and exit from mitosis without properly cleaving cohesin. Multiple SPBs were in fact also observed in many *Scesp1-1* cells at the restrictive temperature (McGrew *et al.*, 1992). *Agesp1Δ* mutants were found to not be viable (supplemental figure 7). Concerning the reduced production of spores in *Agslk19Δ* mutants, the decrease seemed to be to a much smaller extent than in MEN homolog mutants and is likely caused by lower numbers of single SPB nuclei, rather than sporangium malformation.

## FINAL DISCUSSION

## Final Discussion

The system promoting exit from mitosis has developed somewhat differently in the *A. gossypii* lineage, compared to *S. cerevisiae*. Whereas it seems that *AgCdc14* has maintained a central role in the cell cycle as well as a conserved basis of regulation, the underlying pathways controlling this pivotal phosphatase are not conserved as such in *A. gossypii*. Homologs of the MEN still apparently function together as a G-protein coupled kinase cascade at the SPBs, this core signalling unit however seems to be uncoupled from any function in *AgCdc14* release and exiting mitosis. The module appears to play a crucial role in septation, which calls to mind the septation initiation network (SIN) of *S. pombe*, which is required for (*ScCdc14* ortholog) *SpClp1*-dependent septum formation and is largely made up of MEN homologs (supplemental figure 5).

The FEAR network on the other hand seems to be functionally conserved in *A. gossypii*, however in a reduced form. *AgZds1/Zds2* and *AgFob1* do not seem to play a role in *AgCdc14* release, and *AgSlk19* may only be involved as a co-factor in cohesin cleavage, but not in FEAR activation. The reduced redundancy of the remaining system seems to have led to more drastic phenotypes of deletion mutants than in *S. cerevisiae*: *AgSpo12/Bns1* and the putative PP2A regulatory subunit *AgCdc55* have obtained essential status. This is similar to the situation during meiosis I in *S. cerevisiae*, where FEAR is essential for proper *ScCdc14* release, and MEN isn't. Meiosis I division notably takes place without ensuing cytokinesis and likely without other orientational cues.

How the regulatory network controlling exit from mitosis in *A. gossypii* might be wired can only be guessed at this moment, however we propose a rather stripped-down model (figure 40),

Interestingly, calculated sequence identity values for all genes in the system are either particularly high (over 70%) or rather low (below 50%) with no values in between (supplemental figure 2). This pattern may indicate points of particularly high evolutionary pressure on the system. To a certain degree high identity values also reflect areas of the network map that are thought to be still intact:

The only highly conserved FEAR homologs are all part of the putative PP2A<sup>*AgCdc55*</sup> phosphatase. On the MEN side of things, the cascade components *AgTem1*, *AgDbf2/Dbf20* and *AgMob1* are strongly conserved, and it seems that evolution has modified the cellular function of this signalling group by altering upstream and downstream elements, and not the pathway itself. Interestingly *AgBub2* and *AgCdc5* are also highly identical to their *S. cerevisiae* homologs. *Agbub2Δ* mutants, which were not investigated thoroughly in this work, were found to be viable (Sandrine Grava, personal communication). *AgCdc5* will be particularly interesting to study, due to its involvement in both FEAR and MEN in *S. cerevisiae*. Interesting preliminary data has already been gathered (supplemental figure 9).

Can *A. gossypii* be viewed as a “primitive” system? In some ways, probably. Polarized growth is very likely to have predeceased cytokinesis in evolution due to its relative simplicity (clustering of a few factors is certainly more easily accomplished than constriction and controlled fusion of a membrane), and *A. gossypii* may very well resemble primordial organisms taking first steps in cell division. However in the case of *A. gossypii*, we can presume that ancestors were in fact “one nucleus per cell” organisms, and that the current morphology and life style has been attained by the loss of functions once possessed. This transpires from the fact that MEN homologs in several other organisms coordinate cytokinesis with the cell cycle, and from studies suggesting that the evolution of septation in *A. gossypii* is also strongly influenced by significant loss of function over the ages (Andreas Kaufmann, doctoral thesis). However the case, it is safe to say that coordination of nuclear division is bound to less conditions than in budding yeast, and that this is directly reflected in reduced complexity of the regulatory pathways.

What implications do these results bear for *S. cerevisiae*? To answer the question what imposing selective force is responsible for the complexity observed in budding yeast FEAR and MEN, it seems that the purpose of the “extra” components lies first

**Figure 40: Possible wiring diagram of exit from mitosis homologs in *A. gossypii*.** Based on pathways presented in introduction. Minimally reduced by nodes and connections that are suggested to be ruled out by experimental data. Question marks indicate important components where insufficient data has been generated to make presumptions.

and foremost in spatial regulation. The importance of feedback loops and other such circuitry motifs present in these parts of the network is not to be underestimated, however their significance is likely to have gradually grown over time, as they have not been conserved in the *A. gossypii* lineage.

The system described in *A. gossypii* may also provide grounds for clarifying unsolved questions that have been experimentally difficult to tackle in *S. cerevisiae*. It may for example prove useful to determine the precise role of *ScCdc5* within mitotic exit (Its function in MEN is well described, it however remains as yet elusive how exactly *ScCdc5* fits into FEAR). With MEN signalling obsolete, any contribution of *AgCdc5* to *AgCdc14* release could be interpreted as a function within FEAR.

Also, some questions remain open as to how *ScSpo12* antagonizes *ScCdc14* sequestration (apart from interaction with *ScFob1*). Perhaps it will be easier to dissect its mode of action within the “simplified” *AgCdc14* release pathway. In addition, study of *A. gossypii* MEN homologs may be of use to elucidate secondary functions in *S. cerevisiae* (such as their role at the bud neck) which are masked by their essential role in nuclear division.

## APPENDIX

Appendix

Supplemental materials

**Supplemental figure 1: EM images of nuclear structures in *A. gossypii*.** (A) single SPB, (B) duplicated SPB, (C) metaphase and (D) anaphase nuclei. White, dashed lines indicate the visible border between regions of different electron density thought to delimit the nucleolus. White arrows indicate mitotic spindles, asterisks indicate the position of SPBs. Scale bars depict 200 nm. Adapted from Lang *et al.*, 2010a.

**Supplemental figure 2: Amino acid sequence identities.** Plotted against protein length. Blue: *A. gossypii* proteome. Green: Proteins discussed in this thesis (further details in tables provided in results section). (A) AgPph21/Pph22. (B) AgDbf2/Dbf20. (C) AgCdc5. (D) AgCdc55. (E) AgTpd3. (F) AgCdc14. (G) AgCdh1. (H) AgBub2. (I) AgTem1. (J) AgMob1.

**Supplemental figure 7: *Agesp1Δ* mutants.** *Agesp1Δ* germ bubbles after 14 h on nutrients.

**Supplemental figure 8: Predicted domains of 2nd homologs.** Black bars represent predicted features.

**Supplemental figure 9: Preliminary *Agcdc5Δ* *AgCdc14*-GFP.** Preliminary because: 1) only C-terminally verification possible 2) only one transformant obtained 3) mixed phenotype observed: most homokaryotic germlings died very early. This time-lapse series was taken of homokaryotic mycelium that survived the germling stage and grew very slowly on plates. Yellow arrow: Nucleus which attempts to undergo mitosis with partial *AgCdc14* release, however doesn't fully separate. Green arrow: Nucleus which undergoes mitosis apparently without *AgCdc14* release, and with irregular spindle elongation. Time interval: 45 seconds. Maximal projection of 5 Z-planes. Scale bar depicts 10  $\mu$ m. Shift of imaging field between 7th and 8th frame.

## Verification PCRs

All oligos used for verification PCRs are listed further below and were ordered at Microsynth, CH-9436 Balgach. Both N-terminal and C-terminal products were aimed for in deletion mutants, however, in some cases (marked with \*) only one side could be verified due to failed annealing of the oligonucleotides. Calculated PCR fragment sizes are listed below the gel scans. A legend of the gel scan labels as well as generic figures illustrating the different kinds of reaction products are given in Figure 41. Numbers in brackets next to the strain name denote individual strains isolated.

**Figure 41: Verification gel scans.** Top left: DNA ladder scales used on following pages representing Promega 1kb (blue) and Invitrogen 100bp (red) commercial benchtop ladders. Top right: legend of gel scan labels. Bottom: Illustrations of different kinds of PCR products (letters in legend) indicating different genotypes. From top to bottom: Wild-type allele / deletion allele / GFP (or other fluorescent protein) fusion integrated into genomic locus / GFP fusion on plasmid.

**Table 5: Strains used in this study.** Listed alphabetically, except for foreign strains, which are listed last.

## Plasmid list

Plasmid	Description	Derived from	Reference
pMF1	<i>AgTEM1</i> clone	pRS416	This study
pMF2	<i>AgTEM1-yEGFP-GEN3</i>	pMF1	This study
pMF3	(C-ter) <i>AgLTE1-yEGFP-GEN3</i>	pAG7638	This study
pMF8	<i>AgNOP1</i> clone	pRS416	This study
pMF10	<i>AgPDS1-mCherry-NAT1</i>	pAG11556	This study
pMF12	<i>AgNOP1-mCherry-NAT1</i>	pMF8	This study
pAG7638	<i>AgLTE1</i> C-terminus clone	-	Christine Mohr, doctoral thesis
pAG11556	<i>AgPDS1</i> clone	-	Christine Mohr, doctoral thesis
pAGT100	<i>NAT1</i> cassette	-	Kaufmann, 2009
pAGT120	<i>LEU2</i> cassette	-	Kaufmann, 2009
pAGT140	<i>GEN3</i> cassette	-	Kaufmann, 2009
pAGT211	linker- <i>mCherry-NAT1</i>	-	Kaufmann, 2009
pAGT241	linker- <i>yEGFP-GEN3</i>	-	Kaufmann, 2009
pRS416	<i>MCS</i> in <i>lacZ</i>	-	Sikorski and Hieter, 1989
pNUP49-yEGFP	<i>NUP49-yEGFP-GEN3</i>	-	Sandrine Grava, unpublished
pCB50	<i>AgTub4-YFP-AgLEU2</i>	-	Claudia Lang, doctoral thesis
pTUB4-YFP	<i>AgTub4-YFP-AgLEU2 ARS</i>	-	Claudia Lang, doctoral thesis

**Table 6: Plasmids used in this study.** Construction of plasmids descibed in materials and methods section.

## Abbreviations and glossary

aa: amino acids	duplication event
<i>Ag</i> : <i>Ashbya gossypii</i>	o/n: over night
AFM: <i>A. gossypii</i> full medium	ORF: open reading frame
AGD: <i>A. gossypii</i> genome database	ortholog: homolog separated by a speciation event
ALF: <i>A. gossypii</i> low fluorescence medium	paralog: homolog separated by a gene duplication event
APC: anaphase-promoting complex, also known as “cyclosome”	PCR: polymerase chain reaction
ARS: autonomously replicating sequence	PERL: practical extraction and report language
ASC: <i>A. gossypii</i> synthetic complete medium (Michael Köhli, doctoral thesis)	RENT: regulator of nucleolar silencing and telophase exit
ascomycete: sac fungus	RNA: ribonucleic acid
BASF: Badische Anilin- und Soda-Fabrik	rRNA: ribosomal RNA
bp: base pairs	RT: room temperature
Cdc: cell division cycle	SAC: spindle assembly checkpoint
Cdk: cyclin dependent kinase	<i>Sc</i> : <i>Saccharomyces cerevisiae</i>
cMT: cytoplasmic microtubules	SD: standard deviation
D-Box / destruction box: amino acid motif required for APC dependent degradation	SGD: <i>Saccharomyces cerevisiae</i> genome database
DNA: deoxyribonucleic acid	SIN: septation initiation network
dSPB: daughter SPB	<i>Sp</i> : <i>Schizosaccharomyces pombe</i>
GAP: GTPase-activating protein	SPB: spindle pole body
GEF: guanine nucleotide exchange factor	SPOC: spindle positioning checkpoint
GFP: green fluorescent protein	synteny: conserved gene order and orientation
G protein: guanine nucleotide-binding protein	TL: time-lapse
EM: electron microscopy	ts: temperature sensitive
EMBOSS: european molecular biology open software suite	wt: wild-type
FEAR: cdc fourteen early anaphase release	yEGFP: yeast-enhanced GFP
hypha: filamentous fungal cell	YFP: yellow fluorescent protein
ID: identity (of amino acid sequence)	YNB: yeast nitrogen base
IF: immunofluorescence	
kb: kilo-base pair	
mCherry: monomeric Cherry	
MCS: multiple cloning site	
MEN: mitotic exit network	
mSPB: mother SPB	
MTOC: microtubule organizing center	
MT: microtubules	
mycelium: network of branching hyphae	
N: sample size	
N/A: not available	
NES: nuclear export signal	
NLS: nuclear localization signal	
nucleolus: substructure of nucleus and site of rRNA transcription	
ohnolog: homolog separated by a whole genome	

## ACKNOWLEDGEMENTS

## Acknowledgements

I would like to thank Peter Philippsen for all his efforts during my PhD years. His constant support, positive attitude, generosity, interest and scientific input have made the time I have spent in his lab very enjoyable and fruitful.

Special thanks to the members of my thesis committee, Anne Spang and Frank Uhlmann for their thoughts, opinions and contributions to this work.

Thanks to Sandrine and Peter for proof-reading.

Thanks to all present and former members of the Philippsen group for providing such a nice working environment and helping out with everything, from fetching happy-meals to donating AFM plates, giving advice or just joking around.

Thanks also to fellow PhD students from other labs, such as Tommy for being such a chilled-out flat-mate, or Andy and Reto, for granting me admission to their exclusive coffee breaks.

Thanks to Leo, Kühni, Gio and Dominique for generating significant distraction outside of Basel.

Thanks to my whole family for their support over the years and for all the relaxing weekends.

Special thanks to Nathalie Fabienne Manac'h for the many years of adventures (and many more to come). Thanks also for all the support, not to mention the exquisite dining during the final weeks of writing.

## CURRICULUM VITAE

## Curriculum vitae

Mark Robert Finlayson

Born on February 11, 1981  
in Wanganui, New Zealand

### Education:

2001	Matura type C (Mathematics), Kantonsschule, Solothurn
2005	B.Sc. (in Biology) <b>Major in Molecular Biology</b> University of Basel
2006	M.Sc. (in Molecular Biology) <b>Major in Cell Biology</b> University of Basel
2007-2010	PhD project “Investigation of FEAR and MEN pathway homologs in multinucleate cells” University of Basel Supervision: Peter Philippsen Thesis committee: Prof. Anne Spang Prof. Frank Uhlmann

### Contact:

Muespacherstrasse 37  
4055 Basel  
Switzerland  
Mark.Finlayson@gmail.com

### Activities:

Conference: Computational Cell Biology, 2008, Hinxton, UK, poster: “Exit from mitosis in multinucleate cells”.

Meeting: European Meeting on Yeast and Filamentous Fungi, 2008, Université Louis Pasteur, Strasbourg, France, poster: “Exit from mitosis in multinucleate cells”.

Meeting: Systems Biology of a Filamentous Yeast, 2008, Biozentrum, University of Basel, Switzerland, talk: “Exit from mitosis in multinucleate cells”

Meeting: Yeast Genetics and Molecular Biology, 2008, Toronto, ON, Canada, poster: “Evolution of cellular networks: Exit from mitosis in multinucleate hyphae”.

Conference: Cell Growth & Proliferation, 2009, Colby College, Waterville, ME, USA, Poster: “Driven by FEAR. Exit from mitosis in multinucleate hyphae”.

Publication: Lang, C., Grava, S., Finlayson, M., Trimble, R., Philippsen, P., and Jaspersen, S. L. (2010). Structural mutants of the spindle pole body cause distinct alteration of cytoplasmic microtubules and nuclear dynamics in multinucleated hyphae. *Mol Biol Cell* 21, 753-766.

Publication: Finlayson, M. R., Helfer-Hungerbühler, A. K., Philippsen, P. (2011) **Regulation of exit from mitosis in multinucleate *A. gossypii* cells relies on a minimal network of genes.** Accepted for publication in *Mol Biol Cell*.
